The Genus *Mycobacterium*—Nonmedical

SYBE HARTMANS, JAN A. M. DE BONT AND ERKO STACKEBRANDT

Introduction

Because new *Mycobacterium* species are being described in rapid order and because awareness of the importance of these organisms in the clinical and nonclinical environment is increasing, the editors of *The Prokaryotes* think that a thorough coverage of the rapidly growing species should await extensive comparative studies and a deeper analysis of their biotechnological and ecological role. Several genomes of slowly growing mycobacteria have been or are in the process of being sequenced, e.g., several strains of *Mycobacterium tuberculosis*, *Mycobacterium bovis*, *Mycobacterium leprae*, and the two subspecies of *M. avium*. Only one genome of rapidly growing mycobacteria, i.e., *Mycobacterium smegmatis* MC2155 (see The Institute for Genomic research website), has been sequenced; this approach will certainly be applied to more members of these organisms. For the time being, the reader is referred to the recent descriptions of novel species (Table 2) to obtain information on specific properties and to the original chapter by Hartmans and De Bont (1991) in *The Prokaryotes*. The phylogenetic placement of nonmedical strains next to their medically relevant neighbors is shown in Figs. 1–4.

Mycobacteria are aerobic, acid-fast actinomycetes that usually form slightly curved or straight nonmotile rods ($0.2\text{--}0.6 \times 1.0\text{--}10\ \mu\text{m}$). Branching and mycelium-like growth may take place with fragmentation into rods and coccoid elements. Many species form whitish or cream-colored colonies, but especially among the rapid growers, there are also many bright yellow or orange species containing carotenoid pigments (David, 1984). In some cases, the pigments are only formed in response to light (photochromogenic species), but most pigmented species also form these pigments in the dark (scotochromogenic species).

Mycobacterium is the only genus listed in the Family Mycobacteriaceae in *Bergey's Manual of Systematic Bacteriology* (Wayne and Kubica, 1986), but the genus is considered to be closely related to the other mycolic acid-containing gen-

era of cell wall chemotype IV: *Caseobacter*, *Corynebacterium*, *Nocardia* and *Rhodococcus* (Goodfellow and Cross, 1984).

Chemical differentiation of mycobacteria from the other mycolic acid-containing genera is possible by analysis of the fatty acid esters formed upon pyrolysis of the mycolic acid esters, in combination with the identification of the major menaquinone present in the plasma membrane (Table 1). The Ziehl-Neelsen stain for acid fastness, however, remains the most obvious method to quickly identify mycobacteria (Barksdale and Kim, 1977).

Mycobacteria are the causal agents of two important diseases, tuberculosis and leprosy, and there has thus been a significant clinical interest in the two responsible species. This started with the work of Koch (1882), who detected the tubercle bacillus in stained infected tissues. The generic name *Mycobacterium* was introduced by Lehmann and Neumann (1896) to include the tubercle and leprosy bacilli. For many years after this work, isolates other than *M. tuberculosis*, but resembling it in staining characteristics, were described as “atypical mycobacteria.” After the discovery in the early 1950s that several of these “atypical mycobacteria” could also produce disease in humans (see Kubica, 1978), it was recognized that identification of these strains was required. The classification of Runyon, separating the mycobacteria into four groups (photochromogens, scotochromogens, nonphotochromogens, and rapid growers) was introduced in the late 1950s as a systematic base for the description of the “atypical mycobacteria” (Wayne, 1984). This division, based on pigmentation and rate of growth, is still of use to the clinical mycobacteriologist (see The Genus *Mycobacterium*—Medical in this Volume).

The separation of the genus into two major groups on the basis of the growth rate of the individual species forms the basis of mycobacterial taxonomy. Although not exactly following this division, many slow growers are either associated with or the causal agents of human or other animal diseases. Most rapid growers are not known to be associated with human diseases

Table 1. Differential characteristics of the mycolic acid-containing genera of wall chemotype IV.

Genus	Mycolic acids		Predominant menaquinone	N-glycolyl in glycan moiety of cell wall
	Overall size (number of carbons)	Ester pyrolysis products (number of carbons in chain)		
<i>Caseobacter</i>	30–36	14–18	MK-8(H ₂), MK-9(H ₂) ^a	–
<i>Corynebacterium</i>	22–36	8–18	MK-8(H ₂), MK-9(H ₂)	–
<i>Mycobacterium</i>	60–90	22–26	MK-9(H ₂)	+
<i>Nocardia</i>	44–60	12–18	MK-8(H ₄)	+
<i>Rhodococcus</i>	34–64	12–18	MK-8(H ₂), MK-9(H ₂)	+
<i>Tuskamurella</i>	64–78	20–22	MK-9	+

and consequently are often considered as non-pathogens, although in a strict sense, “nonpathogens” may not really exist (Tsukamura, 1984). Rapidly growing mycobacteria are common saprophytes in natural habitats but have received much less attention than the clinically more relevant slow-growing species.

Phylogeny and Taxonomy

Taxonomic studies traditionally have relied heavily on morphological characteristics, but subsequently numerical taxonomy and chemotaxonomic characteristics have played an important role in determining taxonomic relationships. Cell wall and mycolic acid analyses have proved to be of great value in separating the actinomycete genera, while numerical taxonomy has had the most impact on the subgeneric level (Goodfellow and Wayne, 1982). DNA hybridization of genomic DNA and, more recently, 16S rRNA similarity data are of course important tools in determining phylogenetic relations on both the generic and subgeneric levels.

Phylogeny

The number of *Mycobacterium* species has increased from about 40 in 1980 (Skerman et al., 1980) to about 110 in 2004. The description of novel species is paralleled by the development of molecular methods and by the increased recognition that slow growing mycobacteria are clinically important and fast-growing mycobacteria are ecologically important. By the end of 1983, there were 52 described species. Only 6 new species were added between 1984 and 1991 and about 4 new species per year between 1992 and 2003. In 2004, 12 new species were described or are in the process of being validated (Table 2).

The often very close relationship among mycobacterial strains and the finding that the slow growing strains possess a single copy of the *rrn* operon only, thus lacking sequence microheterogeneity, made the 16S rRNA gene an

ideal target to be used in the differentiation of strains (De Smet et al., 1996; Holberg-Petersen et al., 1999). Many mycobacterial species can be differentiated on the basis of the sequence of the variable stretch between positions 175 and 238 (*Escherichia coli* nomenclature; Böddinghaus et al., 1990a; Stahl and Urbance, 1990; Pitulle et al., 1992). More than in other bacterial genera, small differences are used as a basis for describing species (Patel et al., 2000), determining intraspecific subclusters (Böddinghaus et al., 1990b; Frothingham and Wilson, 1994). A specific database of high sequence quality (the Ribosomal Differentiation of Medical Microorganisms database; RIDOM) was specifically established for routine diagnosis of these organisms (Harmsen et al., 2003). For those mycobacterial taxa that cannot be discriminated on the basis of their 16S rRNA gene sequence, other genes, such as *gyrB* (Kasai et al., 2000; Niemann et al., 2000), *hsp65* (Devallois et al., 1997; Ringuet et al., 1999), and intraspecific spacers (De Smet et al., 1995; Roth et al., 2000b), were targeted. In addition, the presence of differences in the sequence of other genes (Aranaz et al., 2003) was used in the differentiation of taxa highly related to *Mycobacterium tuberculosis* and *Mycobacterium bovis*.

In the early 1990s, several studies were published which covered the phylogenetic structure of the fast- and slow-growing mycobacteria (Smida et al., 1988; Rogall et al., 1990a; Stahl and Urbance, 1990; Pitulle et al., 1992). The data by and large supported the clustering of mycobacteria according to their growth behavior and indicated that the mostly clinical, slow growing strains evolved from their fast growing relatives (Pitulle et al., 1992). The genomic separateness of the two groups was supported by a sequence idiosyncrasy: the majority of slow growing strains contained an insert (i.e., a long helix between nucleotide positions 451 and 482 [*E. coli* nomenclature]), while the fast growers contained a short helix only. However, some slow growers, such as *Mycobacterium simiae* and *Mycobacterium triviale*, branching deeply within

^aSkerman et al. (1980 [AL]) refers to the Approved Lists in which the respective descriptions were validated.

their cluster, lacked the long helix, thus showing the signature of their fast-growing ancestors (Pitulle et al., 1992). Since 1990, the vast majority of the species descriptions contained an indication (from 16S rRNA gene sequences) of the phylogenetic position of the novel species. How-

ever, the topologies of most phylogenetic dendrograms differed in detail from each other because of the influence of the treeing algorithm used, the selection of reference sequences, and the addition of novel sequences into the database.

The phylogenetic dendrograms (Figs. 2–4) are from a comprehensive neighbor-joining tree based on 16S rRNA gene sequences of all valid and yet-to-be validated species (Fig. 1). The dendrogram includes new sequences, for which the public records indicated incomplete datasets only (i.e., sequences for type strains of *Mycobacterium agri*, AJ429045; *M. confluentis*, AJ634379; *M. moriokaense*, AJ429044; *M. pulveris*, AJ429046; *M. rhodesiae*, AJ429047; and *M. margaritense*, AJ699399). As compared to the dendrograms based on a very limited dataset in 1992, the complete dataset of *Mycobacterium* type strains has not changed significantly: the rapidly growing strains are more deeply branched (Fig. 1, cluster B) and are ancestors of the slow growing strains (Fig. 1, cluster A). However, it should

be noted that the statistical significance is low for the majority of branching points, indicating that the order at which the species branch from each other is not settled and may change within the group to which they belong when new sequence data are added to the database.

SLOW GROWING MYCOBACTERIA The vast majority of slow growing mycobacteria form three clusters with high intracluster relationships (Fig. 1, cluster A, groups A1–A3). Group A1 contains the well known pathogens such as *Mycobacterium tuberculosis*, *Mycobacterium ulcerans*, *Mycobacterium intracellulare*, *Mycobacterium leprae* and their relatives (Fig. 2). These organisms are characterized by a long helix between position 451 and 482 of the 16S rRNA sequence.

Fig. 1. Schematic graph of a neighbor-joining 16S rRNA gene sequence analysis of type strains of slow growing mycobacterial species. Red triangle: slow growing species containing a long helix between positions 451 and 482; yellow triangle: slow growing species containing a short helix between position 451 and nucleotide position; and gray triangle: fast growing species. Bar: 5% sequence difference.

Fig. 2. Neighbor-joining dendrogram of 16S rRNA gene sequences showing the position of type strains of slow growing mycobacterial species. Numbers at branching points refer to bootstrap values. For references to strain number and 16S rRNA gene sequence accession number, see Table 1. Bar: 5% sequence difference.

Group A2 members, embracing *Mycobacterium simiae*, *Mycobacterium gevanense* and relatives (Fig. 2), however, lack this insert.

Group A3 (Figs. 1 and 3) is interesting from an evolutionary point of view in that this assemblage unites slow growing organisms without the characteristic helix insert (*Mycobacterium shimoidei* and *Mycobacterium triviale*) with other members of this group lacking this insert.

The fourth group of slow growers (Figs. 1 and 3), containing the insert (group A4), occupies a distinctly separate position. The three species *Mycobacterium hiberniae*, *Mycobacterium nonchromogenicum* and *Mycobacterium terrae* cluster next to some fast growing members of *Mycobacterium* (cluster B1). Two species, *Mycobacterium doricum* and *Mycobacterium tusciae*, are defined as slow growing mycobacteria but cluster within the phylogenetic radiation of rapidly growing mycobacteria (Fig. 4).

RAPIDLY GROWING MYCOBACTERIA These organisms form four phylogenetic clusters, three of which (together with two individual lineages defined by *Mycobacterium novocastrense* and *Mycobacterium brumae*) are located at the root of the mycobacterial tree (Figs. 1 and 4). The internal structure allows the definition of four groups (B1–B4), of which only group B4 is well separated from the others. Within group B3, the three species *Mycobacterium abcessus*, *Mycobacterium chelonae* and *Mycobacterium immunogenum* are located at the tip of a longer branch which may indicate that these organisms are subjected to a different evolutionary rate. Interestingly, *Mycobacterium chitae* and *Mycobacterium fallax* (group B1) as well as *Mycobacterium holsaticum* show a closer relatedness to slow growing mycobacteria and thus serve as a bridge between fast and slow growers. Most of the fast growing mycobacterium species have been isolated from environmental samples and some are involved in the degradation of polycyclic aromatic hydrocarbons (e.g., *Mycobacterium vanbaalenii*, *M. hodleri* and *M. frederickbergense*) and pentachlorophenol (*M. chlorophenicum*). Others were isolated from wound infections (*M. goodii* and *M. wolinskyi*), but their role as pathogens has not been evaluated. The pathogenicity of other fast growing mycobacterial species is well studied (members of cluster B3, e.g., *Mycobacterium fortuitum*, *Mycobacterium septicum* and their relatives). The ecological role of most fast growing mycobacteria has yet to be determined.

Taxonomy

On the basis of chemotaxonomic studies, the genus *Mycobacterium* was placed within the CNM (*Corynebacterium*–*Nocardia*–*Mycobacte-*

Fig. 3. Neighbor-joining dendrogram of 16S rRNA gene sequences showing the position of type strains of mycobacterial species and the evolution of slow growers (in red) from fast growing ancestors (in blue). Numbers at branching points refer to bootstrap values. For references to strain number and 16S rRNA gene sequence accession number, see Table 1. Bar: 5% sequence difference.

rium) complex. Together with the genera *Caseobacter*, *Rhodococcus* and *Tsukamurella*, these genera all have cell wall chemotype IV (Lechevalier and Lechevalier, 1970) and contain mycolic acids (Collins et al., 1988).

DNA hybridization studies of the genomic DNA have been performed with a number of mycobacteria (Bradley, 1973; Baess, 1982; Lévy-Frébault et al., 1984; Lévy-Frébault et al., 1986b; Garcia and Taberés, 1986; Imaeda et al., 1988; Hurley et al., 1988; Estrada-Garcia et al., 1989) and have generally confirmed the species status already derived from numerical taxonomy studies (Wayne, 1984). More discriminative techniques involving specific DNA probes hybridizing with total DNA (Zainuddin and Dale, 1989; McFadden et al., 1990) or with DNA amplified with the polymerase chain reaction (PCR; Hartskeerl et al., 1989) have been used, but they have focused mainly on the slowly growing species. Sequences of 16S rRNA have also been obtained by direct sequencing of DNA amplified by the PCR method. They were demonstrated to be useful in the differentiation of mycobacteria at the species level (Rogall et al., 1990b). Clearly, the PCR technique will have a significant impact on the identification of mycobacteria in the near future (also see The Genus *Mycobacterium*—Medical in this Volume). DNA-DNA homology studies can be used to dis-

Fig. 4. Neighbor-joining dendrogram of 16S rRNA gene sequences showing the position of rapidly growing type strains of the genus *Mycobacterium* (in blue). Members in red are slow growing species but they cluster with the fast growers phylogenetically. Numbers at branching points refer to bootstrap values. For references to strain number and 16S rRNA gene sequence accession number, see Table 1. Bar: 5% sequence difference.

criminate between more closely related taxa, e.g., the different species of a genus. Note however that DNA-DNA hybridization data from different laboratories can only be compared when reference strains are included. DNA homology studies with selected strains of *M. tuberculosis*, *M. bovis*, *M. bovis* BCG (Bacillus

Calmette-Guérin), *M. microti* and *M. africanum* revealed that all strains exhibited more than 90% DNA relatedness, whereas DNA relatedness between *M. tuberculosis* and other slowly growing mycobacteria ranged from 9–53% (Imaeda, 1985). Although *M. microti*, *M. tuberculosis*, *M. bovis* and *M. africanum* can be distin-

guished phenotypically, numerical taxonomy places them all in a cluster distinct from other slowly growing mycobacteria (Wayne and Kubica, 1986). The 16S rRNA sequences of 14 *M. tuberculosis*, two *M. bovis* and two *M. africanum* isolates were also identical (Rogall et al., 1990b). Considering the above, it is anticipated that a proposal will be made to reduce these four species to one species of *M. tuberculosis*, which possibly will be subdivided into subspecies (Wayne and Kubica, 1986).

DNA-DNA hybridization studies have also led to a better understanding of the relationship between *M. paratuberculosis* and the MAIS (*M. avium*–*intracellulare*–*scrofulaceum*) complex. The MAIS complex strains have been grouped together on the basis of phenotypic characteristics (Wayne, 1984), but DNA hybridization studies indicate that *M. scrofulaceum* shows little DNA similarity with *M. avium* and *M. intracellulare* (Hurley et al., 1988). The suggestion that *M. avium*, *M. intracellulare* and *M. paratuberculosis* should be grouped together as biovars of a single species is based on these studies (Hurley et al., 1988). The 16S rRNA sequences can however be used to differentiate between representatives of each of these species (Rogall et al., 1990a).

DNA homology studies with rapidly growing mycobacteria have also been performed (Baess, 1982; Lévy-Frébault et al., 1984; Lévy-Frébault et al., 1986b; Garcia and Taberés, 1986). In the study of Baess (1982), *M. chelonae* subsp. *chelonae* and *M. chelonae* subsp. *abscessus* could not be distinguished using the spectrophotometric method, but with the more sensitive S1 nuclease method, the two subspecies were clearly distinct (Lévy-Frébault et al., 1986b). Within the subspecies, homology values were higher than 73% and changes in melting temperature (ΔT_m) less than 2°C, whereas homology values between the *M. chelonae* groups were 26–52% with ΔT_m values of more than 8°C. Both studies indicate that the unrecognized species “*M. perigrinum*,” often grouped within the *M. fortuitum* complex, has been revived as an independent species (Table 2).

Habitats

Mycobacteria have been isolated from a very diverse array of biotopes including material of both mammalian and nonmammalian origin, as for instance fresh and salt water, soil, and dust. Some species of the nonpathogenic saprophytes may also occur as opportunistic pathogens. The pathogenic species and their habitats are covered in The Genus *Mycobacterium*—Medical in this Volume and will only be discussed in this chapter in relation to nonmammalian environments.

Although many *Mycobacterium* species have been isolated from environmental samples, this does not necessarily imply that these strains can all grow under these conditions. Essential in assigning a species to the natural flora of a specific environment is that it should be capable of multiplying actively in these environments (Kazda, 1983). If it lacks this property then it should be regarded as a contaminant. Discriminating between these two possibilities is very difficult because the chance of isolating “contaminating” mycobacteria from environmental samples is quite large as a result of the ability of mycobacteria to survive for very long periods under nongrowth conditions. *Mycobacterium paratuberculosis*, for example, was reported to survive for 252 days in a soil-water slurry (Kazda, 1983).

The most recent reviews on the ecology of mycobacteria are those of Kazda (1983), Collins et al. (1984), and Tsukamura (1984). Kazda (1983) classified the mycobacteria into four groups on the basis of ecologically relevant properties. He distinguished obligate pathogenic, facultative pathogenic, potentially pathogenic, and saprophytic species.

Included in the group of obligate pathogens, which presumably are unable to multiply outside living beings, are the species *M. tuberculosis*, *M. bovis*, *M. africanum*, *M. asiaticum*, *M. malmoense*, *M. microti*, *M. simiae*, *M. szulgai* and *M. haemophilum*. Of these species, *M. tuberculosis* and *M. bovis* have been isolated from wastewater (Kazda, 1983). *Mycobacterium farcinogenes* and *M. shimodei* can also be included in the group of obligate pathogens as they have been isolated from mammalian sources only (Tsukamura, 1982; Wayne and Kubica, 1986).

Kazda assigned *M. leprae*, *M. paratuberculosis* and *M. ulcerans* to the provisional group of the facultative pathogens as their incidence in natural biotopes has not been investigated in detail. Future research may result in the assignment of these species to either the potential or obligate pathogens (Kazda, 1983).

Examples of potential pathogens are *M. avium*, *M. chelonae*, *M. fortuitum*, *M. intracellulare*, *M. kansasii*, *M. marinum*, *M. senegalense*, *M. scrofulaceum* and *M. xenopi* (Kazda, 1983). These species can grow in natural biotopes without losing their pathogenic properties, and they have been isolated from a variety of biotopes (Kazda, 1983; Tsukamura, 1984).

The saprophytic mycobacteria include among others the slowly growing species *M. gordonae*, *M. nonchromogenicum*, *M. triviale*, *M. terrae* and *M. gastri* and most of the rapidly growing species (Table 2), with the exception of *M. chelonae*, *M. fortuitum* and *M. senegalense* and their relatives, which are classified as potential pathogens

(Kazda, 1983). The saprophytic and potentially pathogenic groups (Kazda, 1983) are found in many environments (Tsukamura, 1984) and only occasionally occur as an accompanying flora in pathogenic processes. The ability of organisms from these groups to utilize many different growth substrates and their capacity to survive and multiply under a wide range of environmental conditions apparently enable them to compete successfully with other organisms in many biotopes.

The abundance of the fast-growing species in soils was already demonstrated by Jones and Jenkins (1965). In screening soil samples, 101 acid-fast strains were isolated. Of the 93 isolates studied, five were scotochromogens and all but three of the nonphotochromogens were rapidly growing mycobacteria, forming colonies within 7 days at 25°C.

The most commonly occurring *Mycobacterium* in the environment is probably *M. fortuitum*, as it is often the major *Mycobacterium* species (40–80%) isolated from soil samples (Tsukamura, 1984). Strains of the slowly growing *M. nonchromogenicum* complex (*M. nonchromogenicum*, *M. terrae* and *M. triviale*) and the rapidly growing species *M. aurum*, *M. smegmatis* and *M. agri* have also been isolated frequently from soil samples (Tsukamura, 1984). Isolates from hospital dust were also predominantly *M. fortuitum* (43%), with significant numbers of strains of the *M. nonchromogenicum* complex (25%) and *M. gordonae* (18%), whereas from house dust the majority of the strains isolated belonged to the MAIS (*M. avium-intracellulare-scrofulaceum*) complex (55%), and significant numbers belonged to the *M. nonchromogenicum* complex (23%) and were also *M. gordonae* (11%; Tsukamura, 1984).

The “tap water scotochromogen,” *M. gordonae*, is the strain most often isolated from water samples of various origins (Collins et al., 1984). Besides *M. gordonae*, strains of *M. terrae*, *M. phlei* and *M. fortuitum* have also been isolated at a high frequency from various nonmarine aquatic environments (Viallier and Viallier, 1973). Analysis of municipal water supplies and water supplies in hemodialysis centers found strains of *M. fortuitum*, *M. chelonae*, *M. scrofulaceum*, *M. gordonae* and of the *M. avium* and *M. terrae* complexes (Carson et al., 1988). The average number of mycobacteria detected in the municipal water supplies was 74 ± 42 per 100 ml. Marine water samples, usually from coastal waters, predominantly yielded strains of the MAIS complex, although strains of *M. gordonae* and *M. terrae* were also isolated (Collins et al., 1984).

However, when considering studies on the isolation of various *Mycobacterium* species from

the environment, note that environmental samples are routinely decontaminated and that the distribution of the species isolated need not necessarily reflect the distribution of these species in the original sample. It may well be that certain species, or cells in a particular physiological state, exhibit a higher- or lower-than-average survival rate during the decontamination procedure. Application of the decontamination procedure therefore may result in an over- or underestimate of the prevalence of a particular species.

Another consequence of routinely applied decontamination procedures is that no reliable data can be obtained on the numbers of viable mycobacteria present in natural environments. The actual numbers present in soil samples may also be considerably higher than anticipated from viable counts of nondecontaminated samples because of the hydrophobic characteristics of the mycobacterial cell wall, which may result in significant bacterial adhesion to surfaces.

Isolation

Mycobacteria are not always readily isolated from natural samples. They grow relatively slowly and are therefore easily overgrown by faster-growing organisms. However, taking advantage of the resistance of mycobacteria to adverse conditions, decontamination procedures and selective media have been developed to increase the efficiency of isolation procedures (Kubica and Good, 1981). Most of the decontamination methods were developed for the isolation of mycobacteria from specimens originating from diseased humans or animals and exploit the resistance of the acid-fast mycobacteria to alkaline and acidic conditions. The most commonly applied decontamination procedures involve treatment of the samples with NaOH (2–4%) for 15–30 min at room temperature or at 37°C (Jenkins et al., 1982). Methods for the selective isolation of mycobacteria from environmental samples have been reviewed by Songer (1981), who, besides reviewing decontamination methods, also discussed numerous selective growth media.

Realize however that no information is available on the number and type(s) of mycobacteria that are lost as a result of the decontamination procedure. Furthermore, the selectivity of the growth conditions (medium composition and incubation temperature) also affects the number and species of mycobacteria that eventually are isolated.

Portaels et al. (1988) have recently compared different decontamination procedures and selective media for the isolation of mycobacteria from soil samples. The best results (low contamination

in combination with high positivity rates) were obtained using the following procedure:

Isolation of Mycobacteria from Soil (Portaels et al., 1988)

Add 0.5 g of soil (wet weight) to 5 ml of sterile trypticase soy broth, shake vigorously, and incubate at 37°C for 5 h. After sedimentation of the soil particles, add 5 ml of malachite green (0.2%), 1 ml of cycloheximide (500 µg per ml), and 5 ml of NaOH (1 M) to the supernatant. After 30 min at room temperature, neutralize the mixture with HCl (1 M) and centrifuge at 2,000 g for 20 min. Inoculate the pellet on Ogawa egg medium containing cycloheximide (500 µg per ml). Incubate at 30°C and inspect every 2 weeks until growth is observed.

Ogawa Egg Medium (Tsukamura et al., 1986b)

Add to 100 ml of water containing sodium glutamate (1%) and KH_2PO_4 (1%), 200 ml of whole eggs, 6 ml of glycerol, and 6 ml of a malachite green solution (2%). The medium is made up as slopes by heating for 60 min at 90°C.

Using the above method, mycobacteria were isolated from 91% of the soil samples with only 4% of the tubes being contaminated, i.e., exhibiting growth of non-acid-fast microorganisms within 6 months (Portaels et al., 1988). Omission of cycloheximide, malachite green, or both compounds from the egg medium resulted in contamination rates of 14%, 49%, and 63%, respectively.

The decontamination method and incubation conditions may even select for a specific mycobacterial species. *Mycobacterium moriokaense*, for instance, is the predominant species isolated from soil samples using the following procedure:

Isolation of *M. moriokaense* (Tsukamura et al., 1986b)

Shake soil sample (20 g) with 100 ml of 0.9% NaCl for 30 min and allow to settle for 15 min. Filter the supernatant and centrifuge the filtrate for 20 min at 700 g. Mix the precipitate in the centrifuge tube with 3 ml of KOH (1%). After 5 min, inoculate 0.02 ml portions of this suspension on slopes of Ogawa egg medium. Incubate the inoculated slopes at 42°C for 7–10 days and subculture the colonies.

The nonpigmented acid-fast colonies isolated using the above procedure were characterized as *M. moriokaense* (80%) and as *M. fortuitum* (20%). The strong selectivity of this procedure is probably due to the combination of the relatively high incubation temperature and the short incubation time. Unfortunately, no mention was made of the numbers of any pigmented acid-fast colonies which might also have grown on the slopes (Tsukamura et al., 1986b).

Another approach for selectively isolating mycobacteria is to use specific carbon sources in simple mineral media. Many years ago, Söhngen (1913) demonstrated that paraffin could be used to enrich mycobacteria from soil and water samples. Likewise, enrichment cultures with ethene

as the sole carbon source also exclusively led to the isolation of mycobacteria (Hartmans et al., 1989). Other genera, for instance *Xanthobacter* and *Nocardia* species, may also grow on ethene (Van Ginkel et al., 1987b). However, the very low growth rates of these species with ethene may explain why enrichment cultures with ethene result in the isolation of the faster-growing mycobacteria.

Morpholine (1-oxa-4-azacyclohexane), which for many years was considered nonbiodegradable because of its persistence in waste-water-treatment plants, has recently been demonstrated to be degraded by *Mycobacterium* isolates (Cech et al., 1988; Knapp and Brown, 1988). All strains isolated on morpholine from municipal activated sludge systems and river water were identified as mycobacteria (Knapp and Brown, 1988).

Another approach combines the selectivity of a single carbon source with the selectivity of an antibiotic in enrichment cultures. Gram-positive methanol-utilizing bacteria were isolated from different soil samples with methanol as carbon source in the presence of the antibiotic polymyxin B (Urakami and Yano, 1989). The 14 isolates were all very similar and were identified as mycobacteria closely resembling *M. fortuitum*. The growth rates with methanol, though, varied quite significantly. Enrichment procedures on methanol in the absence of polymyxin B usually result in the isolation of Gram-negative genera.

Although mycobacteria are isolated quite easily from many different environments, they are difficult to quantify, especially in heterogeneous matrices such as soil. As mentioned by Songer (1981), the attachment of mycobacteria to surfaces has not yet been investigated. Considering the hydrophobic character of mycobacteria (Van Loosdrecht et al., 1987), conceivably a large percentage of the mycobacteria present in soil adhere to the surfaces of solids. Biofouling of cellulose diacetate membranes used in reverse-osmosis water purification plants is an example of this characteristic. It has been proposed that the initial step in this process is the attachment of mycobacteria (Ridgway et al., 1984). Therefore, many of the mycobacteria present in environmental samples may be overlooked, especially if interfaces are present.

Cultivation

Mycobacteria can utilize a wide range of carbon compounds. Very often glycerol is designated the preferred carbon since it is utilized as sole source of carbon and energy by all cultivable mycobacteria (Ratledge, 1982b). For clinical isolates, an absolute requirement for carbon diox-

ide has been reported (Ratlledge, 1982b). It has been observed repeatedly that the lag phase of rapidly growing mycobacteria is shortened considerably when liquid cultures are incubated stationary rather than shaken. This effect may be due to a stimulatory effect of carbon dioxide accumulating in the medium of the stationary culture.

Mycobacteria can use a variety of nitrogen sources, including amino acids and ammonium. In many of the frequently used media for the cultivation of mycobacteria, asparagine is the nitrogen source (Jenkins et al., 1982). Many species can also reduce nitrate (Table 3) and use it as a source of nitrogen. Mycobacteria cannot fix nitrogen. The “*M. flavum*” 301 capable of fixing nitrogen (Ratlledge, 1982b) is in fact a *Xanthobacter flavus* strain (see The Genus *Xanthobacter* in Volume 5). Table 3 lists a number of charac-

teristics of rapidly growing species that are useful in identification.

Most mycobacteria do not require any specific growth factors or vitamins in the growth medium. Exceptions are *M. haemophilum*, which requires hemin, and *M. paratuberculosis*, which requires mycobactin, and of course *M. leprae*, which has until now not been cultivated in vitro (Goodfellow and Wayne, 1982).

Problematic in the cultivation of many strains of mycobacteria in liquid culture is the tendency of these organisms to form aggregates and to adhere to the surfaces of growth vessels, probably as a result of the hydrophobic nature of the cell wall. Detergents such as Tween 80 are therefore often added to the growth medium to reduce clumping and to stimulate growth (Ratlledge, 1982b). Owing to this tendency of most mycobacteria to form clumps

Table 3. Identifying characteristics of some rapidly growing species of mycobacteria.

and to adhere to the surfaces of laboratory fermentors, there have been very few studies of mycobacteria using continuous cultures. One exception was reported by Lowrie et al. (1979). Using a special fermentor in which all stainless steel had been replaced by glass, Teflon, or titanium, *M. bovis* BCG and *M. microti* were grown with 0.08% Tween 80 in the growth medium and by aerating with air containing 5% carbon dioxide. The air supply was introduced in the gas phase of the fermentor, and the stirring rate was kept low to prevent the formation of bubbles.

Some species, however, may be grown in chemostat cultures without having to take any specific precautions. *Mycobacterium phlei* can be grown dispersed in a fermentor (Girbal et al., 1989) without the addition of a detergent, and consequently it has been used quite often for metabolic studies (Ratledge, 1982b). Two other examples of mycobacteria cultivated in continuous culture without detergents are *M. aurum* strain L1 growing on vinyl chloride (Hartmans and De Bont, 1992) and the ethene-utilizing strain E3 growing on ethene (Van Ginkel et al., 1987a).

The mineral salts medium (Wiegant and De Bont, 1980) used in the chemostat studies of *M. aurum* L1 contained 0.2 ml of the Vishniac and Santer (1957) trace element solution per liter. Subsequent chemostat studies using this medium (S. Hartmans and J. A. M. de Bont, unpublished observations) with vinyl chloride as the carbon source revealed that the culture was iron-limited rather than carbon-limited. An improved mineral salts medium with an increased iron content was therefore formulated.

Basal Mineral Salts Medium for the Cultivation of Mycobacteria

K ₂ HPO ₄	1.55 g
NaH ₂ PO ₄ · 2H ₂ O	0.85 g
(NH ₄) ₂ SO ₄	2.0 g
MgCl ₂ · 6H ₂ O	0.1 g
EDTA	10 mg
ZnSO ₄ · 7H ₂ O	2 mg
CaCl ₂ · 2H ₂ O	1 mg
FeSO ₄ · 7H ₂ O	5 mg
Na ₂ MoO ₄ · 2H ₂ O	0.2 mg
CuSO ₄ · 5H ₂ O	0.2 mg
CoCl ₂ · 6H ₂ O	0.4 mg
MnCl ₂ · 2H ₂ O	1 mg
Deionized water	1 liter

Identification

The simplest test for discriminating mycobacteria from other prokaryotes is the Ziehl-Neelsen acid-fast stain. Mycobacteria stained with carbol fuchsin resist decolorization with hydrochloric

acid-alcohol. Barksdale and Kim (1977) have termed this property "mycobacterial acid-fastness" or acid-alcohol-fastness, in contrast to the acid-fastness of several other mycolic acid-containing genera, which resist decolorization with dilute mineral acids but which can be decolorized with hydrochloric acid-alcohol. A detailed discussion of the acid-fast stain is presented in the excellent review of Barksdale and Kim (1977).

An alternative method to reliably distinguish mycobacteria from other genera containing mycolic acids (Table 1) is to analyze the mycolic acid methyl esters by thin-layer chromatography (TLC; Minnikin et al., 1980b; Daffé et al., 1983) and to characterize the major menaquinone (Collins et al., 1977). Alternatively, the fatty acid methyl esters formed during pyrolysis gas liquid chromatography of mycolic acid methyl esters can also be analyzed (Kusaka and Mori, 1986).

Identification schemes for mycobacteria are based on a clear distinction between slowly growing and rapidly growing species. Species forming colonies from dilute inocula within 7 days under optimal conditions are classified as rapid growers. Those requiring more than 7 days are designated slow growers. The difference in growth rates is actually quite distinct, with the slow growers usually requiring 10 days or more to form colonies, whereas all rapidly growing species, including the relatively slowly growing *M. flavescens* and *M. thermoresistibile*, form colonies within 4–5 days (Jenkins et al., 1982).

It has been argued that the importance attributed to this characteristic may lead to erroneous results in the identification of mycobacteria, as isolates are usually only compared with known species of the same growth rate category. However, evidence that the majority of the rapidly growing and slowly growing mycobacteria are also clearly separated by 16S RNA studies (Stahl and Urbance, 1990; see Figs 1 and 4) supports the significance usually attributed to this characteristic in identifying mycobacteria.

The identification of slowly growing strains is described in *The Genus Mycobacterium—Medical* in this Volume as well as in other reviews (Jenkins et al., 1982; Wayne, 1984; Wayne and Kubica, 1986).

Identification of Rapidly Growing Mycobacteria

Identification of rapidly growing mycobacteria can be based on a number of characteristics. Chromogenicity is often used as an initial criterion, primarily of course because of its obvious nature. Numerical studies based on a large number of biochemical and physiological properties

have been used to define the presently accepted species, and consequently many of these characteristics can be used in the identification of new isolates. Chemical analyses of cell constituents such as mycolic acids and mycobactins are also very powerful tools in the identification of mycobacteria. DNA analyses including hybridization studies with specific probes and the identification of specific sequences are the most recently developed techniques in mycobacterial identification.

Chromogenicity and Morphology

Chromogenicity is often used as a convenient criterion for identifying or classifying mycobacterial species, but some caution should be taken, as the significance of pigment production in the physiology of mycobacterial species and its taxonomic value are not very well studied (Kaneda et al., 1988). Thus, novel isolates should be compared with the pigmented as well as with the nonpigmented species (e.g., Tsukamura et al., 1986b). When determining chromogenic properties, the effect of light on pigmentation or even on growth itself should also be considered (De Bont et al., 1980).

A description of the morphological characteristics of the different species has been given by Wayne and Kubica (1986), although, according to Tsukamura et al. (1981b), colonial morphology is not very useful in differentiating mycobacterial species.

Biochemical and Physiological Characteristics

A probability matrix for the identification of the slowly growing mycobacteria has been developed on the basis of a large pool of collected data (Wayne et al., 1980). Although many species of rapidly growing mycobacteria also have been subjected to numerical analysis of a large number of biochemical characteristics (Saito et al., 1977; Tsukamura, 1981a; Tsukamura et al., 1981b; Tsukamura et al., 1983c), such a probability matrix has not yet been developed for the rapidly growing species (Wayne, 1984). Identification of the many rapidly growing mycobacterial species that have been proposed during the last 10 years was, however, usually based on studies involving numerical analysis (Kazda, 1980; Tsukamura, 1981a; Tsukamura et al., 1981b; Tsukamura, 1982; Tsukamura et al., 1983a; Tsukamura et al., 1983b; Tsukamura et al., 1983c; Tsukamura et al., 1986b; Lévy-Frébault et al., 1983; Tsukamura and Ichiyama, 1986a; Padgett and Moshier, 1987). Besides the numerical taxonomic data, additional criteria such as DNA hybridization experiments are generally required to warrant the proposal of a new species (Wayne, 1984).

On the basis of a number of these numerical analysis studies of a large number of strains (Kubica et al., 1972; Saito et al., 1977; Tsukamura, 1981a; Tsukamura et al., 1981b; Tsukamura et al., 1983c; Tsukamura and Ichiyama, 1986a), we have listed several physiological and biochemical characteristics which should be of help in the identification of newly isolated rapidly growing species (Table 3). A detailed description of the methods is given by Vestal (1975). The diagnostic table for rapidly growing species published by Wayne and Kubica (1986) and the references cited therein are also very useful.

Generally, additional tests, such as mycolic acid analysis and DNA-hybridization experiments, are required before an exact identification can be made. Identification of strains of the "*M. parafortuitum* complex," which includes *M. parafortuitum*, *M. diernhoferi*, *M. aurum* and *M. neoaurum*, for example, is sometimes rather difficult. Several strains that clustered with the type strain of *M. neoaurum* in the numerical study of Saito et al. (1977) clustered with the *M. aurum* type strain in a subsequent study by Tsukamura et al. (1983c). In the second study, the above species and the novel species *M. austroafricanum* could be separated satisfactorily. Nevertheless, in view of the similarities observed, the preservation of the *M. parafortuitum* complex containing the five species mentioned above was considered to be justified (Tsukamura et al., 1983c).

The identification of *M. fortuitum* is another example showing that a small number of tests is not sufficient for identifying strains of rapidly growing mycobacteria. This clinically most important rapidly growing species is often identified solely on the basis of its positive 3-day arylsulfatase test. To distinguish *M. fortuitum* from *M. chelonae*, NaCl tolerance, nitrate reduction, and Fe uptake are also often determined (Kubica and Good, 1981). However, as can be seen in Table 3, several other nonphotochromogenic species are also positive in the 3-day arylsulfatase test.

Chemical Analysis of the Mycobacterial Cell

Cell wall and fatty acid analysis has had much impact on the classification of those Gram-positive prokaryotes that have wall chemotype IV (Goodfellow and Cross, 1984), i.e., prokaryotes with a cell wall containing *meso*-diaminopimelic acid (*meso*-A₂pm), arabinose, and galactose (Lechevalier and Lechevalier, 1970). In the mycobacterial peptidoglycan, the peptidoglycan residues are *N*-glycolated rather than *N*-acetylated as in most other *meso*-A₂pm containing prokaryotes (Brennan, 1988; Table 1). Also very characteristic for mycobacteria is the

lipid-rich thick cell envelope containing very long-chain mycolic acids (Draper, 1982; Minnikin and O'Donnell, 1984a; Rastogi et al., 1986; Mamadou et al., 1989; Table 1). The characteristic mycolic acids have received much attention in relation to the identification of mycobacteria, especially at the species level.

Mycolic acids are high-molecular-weight, 3-hydroxy fatty acids substituted with an aliphatic side chain at the C₂ position (Fig. 5). The molecular mass of mycobacterial mycolic acids varies from C₆₀ to C₉₀ (Table 1). Pyrolysis of the methyl esters of mycobacterial mycolic acids yields long-chain meroaldehydes and fatty acid methyl esters (Fig. 6) with chain lengths of 22–26 carbon atoms (Table 1). This is a very useful characteristic in separating mycobacteria from the other mycolic acid-containing genera, although discrimination between the genera *Tsukamurella* and *Mycobacterium* also requires identification of the major menaquinone (Table 1).

Methanolysates of mycobacterial mycolic acids can be resolved into several classes based on the presence or absence of different functional groups in the longer carbon chain, i.e., R₁ in Fig. 5, of the mycolic acid molecule. Both one-dimensional (Daffé et al., 1983) and two-dimensional (Minnikin et al., 1980b) TLC methods have been used. The least polar compounds are termed "α-mycolic acids" and "α'-mycolic acids." They do not contain any oxygen functions apart from the 3-hydroxy and carboxy functions. In the more polar mycolic acids, the longer chain is substituted with methoxy, keto, epoxy, or carboxy functions (Minnikin, 1982). The various epoxy mycolic acids produce differing characteristic TLC patterns, depending on the method by which the methanolysate (acidic or basic methanolysis) was prepared (Minnikin et al., 1984b).

The predominant α-mycolic acids generally contain 74–82 carbon atoms, whereas the α'-mycolic acids are of a lower molecular weight,

with the predominant type containing 60–68 carbon atoms (Kaneda et al., 1988). Five different types of long-chain α-mycolic acids have been separated and identified using argentation TLC, gas chromatography, and mass spectrometry (Minnikin et al., 1984c; Kaneda et al., 1988). These types are I, dicyclopropanoyl; II, monocyclopropanoyl monoenoic; III, methylated monocyclopropanoyl monoenoic; IV, dienic; and V, methylated dienic.

The α'-mycolic acids generally contain only one or two double bonds without any cyclopropanoyl functions (Kaneda et al., 1988). Very often (e.g., Collins et al., 1988) the α-mycolic acids of mycobacteria are described as always containing one or two double bonds. This is probably due to the fact that mycolic acids containing a cyclopropanoyl ring and mycolic acids containing a double bond are not separated by TLC. In fact, many species contain only dicyclopropanoyl α-mycolic acids without any double bonds as shown in Table 4, which lists the mycolic acid content by species (Kaneda et al., 1988).

For a number of species, e.g., *M. fortuitum*, *M. smegmatis* (Minnikin et al., 1984b), *M. phlei*, *M. thermoresistibile* (Lévy-Frébault et al., 1986a) and *M. chitae* (Minnikin et al., 1985), the mycolic acids of large numbers of strains have been analyzed, all resulting in a characteristic pattern for each species. Analysis of seven *M. aurum* strains, however, revealed two different mycolic acid patterns (Table 4), with two strains also containing α'-mycolic acids. This discrepancy was also observed by Lanéelle et al. (1988).

The composition of the α- and α'-mycolic acids of a number of strains has been further analyzed by Kaneda et al. (1988) using gas chromatography and mass spectrometry. These authors separated the rapid growers into three groups on the basis of the types of α-mycolic acids present. Group A only contained dienic α-mycolic acids, group B contained α-mycolic acids containing double bonds and cyclopropanoyl rings, and group C only contained dicyclopropanoyl α-mycolic acids. Group A could be further divided into two groups on the basis of the number of double bonds in the α'-mycolic acids (Table 4). No α'-mycolic acids were detected in *M. gilvum* by Kaneda et al. (1988), whereas several other authors reported that TLC detected α'-mycolic acids in this species. Unfortunately, *M. fallax* was

not included in the study of Kaneda et al. (1988), as *M. fallax* was previously reported to contain unique α -mycolic acids containing three double bonds (Lévy-Frébault et al., 1983). Comparison of the data from these authors, however, also reveals a discrepancy in the reported composition of α -mycolic acids of *M. triviale*. Lévy-Frébault et al. (1983) could not detect unsaturated α -mycolic acids in the type strain of *M. triviale*, whereas Kaneda et al. (1988) detected only dienoic α -mycolic acids in the *M. triviale* strain they analyzed.

The chain lengths of the fatty acid esters released upon pyrolysis of mycolic acid methyl esters have also been analyzed for a number of

strains (Table 4). Usually only the major chain length is reported. With the exception of *M. aurum* and *M. diernhoferi* (Table 4), no contradictory results were reported. *M. aurum* (ATCC 25793) contained almost equal amounts of C₂₂ and C₂₄ (Kusaka and Mori, 1986), whereas *M. aurum* (ATCC 25797) mainly contained C₂₄ (Valero-Guillén and Martín-Luengo, 1986), while the type strain *M. aurum* (ATCC 23366) only contained C₂₂ (Valero-Guillén and Martín-Luengo, 1986; Lanéelle et al., 1988) although it had previously been reported to contain mainly C₂₄ (Daffé et al., 1983).

As the analysis of mycobacterial mycolic acid methyl esters by TLC provides a sensitive and

relatively easy method to determine mycolic acid patterns, the technique clearly can be of great use in the identification of mycobacteria and in mycobacterial systematics. For a number of species, however, more strains need to be analyzed to confirm the consistency of this characteristic within the species. Especially the situation observed within the *M. aurum* species requires further research, possibly resulting in the reassignment of several strains presently recognized as belonging to this species or to other species or subspecies. These studies should be combined with the data from biochemical numerical studies. The chain length of the fatty acid methyl ester formed during pyrolysis may be of additional use in characterizing new isolates. The detailed characterization of the α -mycolic acids, as was reported by Kaneda et al. (1988), would seem to be less practical in view of the required analytical equipment.

The use of mycobactins (lipid-soluble intracellular siderophores of mycobacteria) as chemotaxonomic markers was proposed in the past. Their use was, however, often hampered by the difficulty of acquiring sufficient amounts of material for analysis. Mycobactin yields of 1–8% (w/w) were reported for *M. smegmatis* using a simple glycerol/asparagine/phosphate medium solidified with agar (Hall and Ratledge, 1982). Subsequently, the same method was used to analyze the mycobactins of a number of different rapidly growing mycobacteria using TLC and high-performance liquid chromatography (HPLC; Hall and Ratledge, 1984). With most strains tested, mycobactin yields of 4–6% (w/w) were obtained. *Mycobacterium aurum*, *M. parafortuitum* and *M. thermoresistibile* did not form detectable amounts of mycobactin under the standard conditions, though more than two-thirds of these strains did yield mycobactins (3–5%) when grown on glucose/yeast extract/agar. The *M. vaccae*, *M. chelonae* subsp. *chelonae*, and *M. komossense* strains tested did not produce detectable amounts of mycobactin on either growth medium. TLC analysis of 32 strains of 15 species of rapidly growing mycobacteria using two different solvent systems revealed that all strains within a single species (except for *M. flavescens*) produced mycobactin with the same R_f value.

TLC analysis of mycobactins is a relatively simple technique, and on the basis of the data presented by Hall and Ratledge (1984), it appears to be a very useful chemotaxonomic character with a high discriminatory power. However, just as in the case of mycolic acid patterns, much larger numbers of strains have to be analyzed to confirm the chemotaxonomic utility of the mycobactin R_f value in identifying mycobacterial species.

Physiology

The physiology of mycobacteria will not be discussed in an exhaustive manner in this chapter as this subject has been dealt with in excellent reviews by Ratledge (Ratledge, 1976; Ratledge, 1982b) and also in the reviews of Ramakrishnan et al. (1972) and Masood et al. (1985). Furthermore, contrary to what was sometimes suspected in the past, mycobacterial physiology differs from that of other aerobic saprophytes only in minor aspects. This section will focus on the areas of mycobacterial physiology that are typical for the genus. The metabolism of unsaturated gaseous hydrocarbons is one area where the role of the mycobacteria is especially important. Another area to be discussed is fatty acid biosynthesis, because mycobacteria clearly differ in this respect from most other prokaryotes. Reserve materials, fatty acid composition, and iron uptake are also discussed.

Catabolic Activities

Mycobacteria are metabolically versatile organisms. They grow not only on common substrates such as sugars, alcohols, and organic acids, but also on a large variety of hydrocarbons including branched-chain, unsaturated, aromatic, and cyclic hydrocarbons (Söhngen, 1913; Lukins and Foster, 1963). Mycobacteria also degrade polycyclic aromatic hydrocarbons, such as pyrene (Heitkamp et al., 1988a; Heitkamp et al., 1988b) and phenanthrene (Guerin and Jones, 1988). Some mycobacteria grow on the simple one-carbon compounds methanol and methylamines (Kato et al., 1988; Urakami and Yano, 1989). In one strain of *M. gastri*, 3-hexulose-6-phosphate synthase was present, indicating formaldehyde incorporation via the ribulose-monophosphate pathway in this strain (Kato et al., 1988). Autotrophic growth on carbon dioxide and hydrogen gas of several strains of *M. smegmatis*, *M. marinum* and *M. fortuitum* was already reported by Lukins and Foster in 1963 (20% of the strains tested). The propene-utilizing strain called "*Mycobacterium* Py1" (De Bont et al., 1980) also grew autotrophically. Under these conditions, ribulose-1,5-bisphosphate carboxylase and a membrane-bound hydrogenase were induced (C. G. van Ginkel and J. A. M. de Bont, unpublished observations). Reports in the older literature on mycobacteria growing on methane should be treated skeptically since such isolates were either lost before a rigorous identification was performed or no longer grew on methane when investigated by others later.

Metabolism of Gaseous Hydrocarbons

In the past, one of the incentives for studying microorganisms degrading gaseous hydrocarbons was the suspected relation between the numbers of these organisms present in soil and the presence of fossil fuel reserves. Such a relationship has, however, not been substantiated (Brisbane and Ladd, 1972).

Growth of mycobacteria with the C₂ hydrocarbons ethane and ethene (ethylene) has been described several times. Using ethane as carbon source, Davis et al. (1956) isolated several types of ethane-utilizing bacteria, with mycobacteria predominating. The isolated mycobacteria could be divided into two groups on the basis of their capacity to grow on complex media. About half of the isolates did not grow on nutrient agar or with glycerol as sole carbon source and were placed in a separate novel species, "*M. paraffinicum*." The assignment of "*M. paraffinicum*" to the genus *Mycobacterium* is, however, questionable, as it was shown to contain trehalose mycolates of a relatively low molecular weight (Minnikin and Goodfellow, 1980a). Using ethene as carbon source, several mycobacteria were isolated (De Bont, 1976). *Mycobacterium* E20 also grew with ethane. Ethane metabolism was via acetate and ethene metabolism via epoxyethane (De Bont and Harder, 1978). Epoxyethane was further degraded to acetyl-coenzyme (Co)A in a CoA- and nicotinamide adenine dinucleotide (NAD)-dependent reaction (De Bont and Harder, 1978). In contrast to the alkene monooxygenase induced by growth on ethene, the ethane hydroxylase activity of *Mycobacterium* E20 could not be detected in cell-free extracts of ethane-grown cells (De Bont et al., 1979).

Of the short-chain hydrocarbons, the metabolism of propane and its derivatives has received the most attention in the past. The initial step in propane degradation has been the subject of speculation and study for quite some time. Oxidation of both the primary and secondary carbon atoms of propane has been shown to occur (Perry, 1980). *Mycobacterium vaccae* JOB5 has been used in several cases to study three-carbon metabolism (see Perry, 1980). In this strain, acetone and acetol as well as acetate have been detected as intermediates in propane metabolism. These observations contrast with acetone metabolism in several unidentified Gram-positive bacteria that degrade acetone via pyruvate (Taylor et al., 1980).

Mycobacterium Py1, which was isolated with propene as carbon source (De Bont et al., 1980), did not grow on propane or acetone. However, it utilized acetol, which was oxidatively transformed into acetate and formaldehyde by acetol monooxygenase through a Bayer-Villiger type of

reaction (Hartmans and de Bont, 1986). Propene metabolism in *Mycobacterium* Py1 proceeds via an initial oxidation to epoxypropane, which is subsequently carboxylated, presumably to acetoacetate.

Fatty Acid Biosynthesis

Mycobacterial lipids have been the subject of numerous studies, often with an emphasis on taxonomic aspects (Ratledge, 1982a; Minnikin, 1982; Brennan, 1988). Besides the characteristic lipid-rich cell wall, mycobacteria also differ from most other prokaryotes in aspects of fatty acid biosynthesis. Fatty acid synthetases are generally divided into two types: the type I "eukaryotic" system and the type II "prokaryotic" system. The type II system, which readily dissociates into separate proteins with discrete catalytic activities, has been detected in all bacteria studied, with the exception of some mycobacteria and corynebacteria. The type I system present in animals and eukaryotic microorganisms has also been found in *M. smegmatis* and *Corynebacterium diphtheriae*.

Fatty acid biosynthesis in *M. smegmatis* has been studied in detail by Bloch and coworkers (Bloch, 1977). They described two fatty acid synthetase (FAS) activities in this species. One is the extensively studied multienzyme complex called "FAS-I," which is probably very much like the FAS of eukaryotes. FAS-I is, however, unique in that it produces both very long (C₂₄ and C₂₆) as well as the more common (C₁₆ and C₁₈) saturated CoA esters of fatty acids, and its activity is stimulated by certain polysaccharides. The 3-O-methylmannose polysaccharide (MMP) and 6-O-methylglucose polysaccharide (MGLP) affect the K_m for both acetyl-CoA and malonyl-CoA and can bind palmitoyl-CoA, thus restricting further chain elongation and consequently influencing the bimodal product distribution. The biosynthesis of these polysaccharides has recently been studied by Ballou and coworkers (Weisman and Ballou, 1984a; Weisman and Ballou, 1984b; Kamisango et al., 1987).

The second FAS in *M. smegmatis* studied by Bloch and coworkers is similar to the type II FAS found in other prokaryotes in its requirement for an acyl-carrier protein (ACP). De novo fatty acid synthesis is, however, not observed with the type II FAS of *M. smegmatis*, so that it should actually be regarded as a fatty-acid-elongating system, elongating acyl-CoA esters of C₁₆ to C₂₈ (Odriozola et al., 1977). The polysaccharides which affect the type I FAS do not affect the type II elongating system of *M. smegmatis*, and FAS II activity is not inhibited by palmitoyl-CoA.

Another fatty-acid-elongation system (FES I), isolated from *M. smegmatis*, requires acetyl-CoA and is apparently ACP-independent (Shimakata

et al., 1977). It exhibits optimal activity with the C_8 and C_{10} acetyl-CoA esters. The enzymatic activities of this fatty acid-elongation system, however, under physiological conditions may be involved in the β -oxidation of fatty acids and utilize the stereospecificity of the 3-oxoacyl-CoA reductase, which forms L-hydroxyacyl-CoA esters (Shimakata et al., 1979). L-Hydroxyacyl-CoA esters normally are intermediates in the degradation of fatty acids.

Subsequently, a third elongation system has been described which was apparently also ACP-independent, but which required malonyl-CoA instead of acetyl-CoA. This FES exhibits activity with C_{10} to C_{24} acetyl-CoA esters, with an optimum for stearyl-CoA (Kikuchi and Kusaka, 1982). Also, a very long-chain fatty acid-elongation system was isolated from *M. avium* (Kikuchi et al., 1989), which possibly is involved in the synthesis of mycolic acids. It differs from the ACP-independent, malonyl-CoA-incorporating-elongation system of *M. smegmatis* (Kikuchi and Kusaka, 1982) in its cofactor requirements and its sensitivity towards isoniazid. The authors suggest that isoniazid possibly affects the 3-oxoacyl-CoA and enoyl-CoA reductase activities. This would explain the previously observed effect of isoniazid specifically inhibiting the synthesis of mycolic acids (Winder, 1982).

In contrast to the common bacterial pathway of unsaturated fatty acid formation by elongation of decenoyl-CoA, resulting in the formation of palmitoleic and *cis*-vaccenic ($C_{18:1}\Delta^{11}$) acid, biosynthesis of unsaturated fatty acids in mycobacteria is accomplished by desaturation of stearyl-CoA to oleoyl-CoA, and to a lesser extent palmitoyl-CoA to palmitoleoyl-CoA, by the particulate Δ^9 desaturase (Ratlidge, 1982a). A very long-chain, soluble, fatty acid Δ^{15} desaturase was isolated from *M. smegmatis*, which exhibited optimal activity with lignoceroyl-CoA ($C_{24:0}$; Kikuchi and Kusaka, 1986).

The most common mycobacterial branched-chain fatty acid is tuberculostearic acid (D-10-methylstearic acid). It is formed by methylation of oleic acid residues already esterified in phospholipids (Ratlidge, 1982a). The methyl group is derived from *S*-adenosylmethionine.

The various different fatty acid synthases and elongating systems that have been found in mycobacteria are of course a reflection of the many different fatty acids present in these organisms. The different constituents will not be discussed in detail here, as excellent reviews are available (Minnikin, 1982; Brennan, 1988).

Reserve Materials

Besides the mycolic acid composition (see Identification), other lipid components of mycobacteria

have also been studied. Mycobacteria can contain considerable amounts of triacylglycerols, especially in glycerol-grown cells, resulting in the formation of fat bodies (lipid vacuoles; Brennan, 1988). These lipids may be utilized as a reserve material, though glycogen and trehalose have also been suggested as reserve materials (Ratlidge, 1982b). In nitrogen-limited batch cultures of *M. phlei*, both lipid and glycogen accumulation were observed (Antoine and Tepper, 1969). Transfer of these cells to a medium with a high nitrogen content without carbon resulted in restoration of growth and a decrease of the lipid and glycogen content. Similar experiments with *M. smegmatis* (Elbein and Mitchell, 1973) focused on glycogen and trehalose levels. *Mycobacterium smegmatis* grown under nitrogen-limiting conditions had an increased glycogen content, which was rapidly utilized when these cells were transferred to a medium containing sufficient carbon and nitrogen. The trehalose levels were more or less the same under all growth conditions, indicating that under these conditions trehalose is not a reserve material, although the turnover rates were very high (Elbein and Mitchell, 1973).

Starvation experiments performed with *Mycobacterium* sp. strain E3, a "*M. parafortuitum* complex" species, grown under nitrogen or carbon limitation in chemostat cultures have been performed (Habets-Crützen, 1985a). Cells grown under nitrogen limitation contained 10 times more glycogen and only 50% more trehalose and lipid than cells grown under carbon limitation. The reserve materials of these cells were monitored during a 2-day incubation in buffer in the absence of carbon or nitrogen sources. Trehalose levels fell from 2–3% to less than 0.5% within 8 h. The lipid/protein ratio remained constant during the 2-day starvation experiment. Glycogen was only consumed in the cells grown under nitrogen limitation. The 2% glycogen present in cells grown under carbon limitation was not consumed during the 2-day-starvation experiment. Experiments monitoring the NADH-dependent oxidation of propene to 1,2-epoxypropane by starving cells showed that nitrogen-limited-grown cells, containing the higher glycogen levels, produced more of the epoxide (De Haan et al., 1991).

Lipid Composition

The phospholipids of *M. smegmatis* and *M. phlei* have been studied in some detail (Dhariwal et al., 1976). Major phospholipids present in mycobacteria are phosphatidylinositol, phosphatidylethanolamine, diphosphatidylglycerol (cardiolipin), and the phosphatidylinositol mannosides. The phosphatidylinositol mannosides

are highly characteristic for actinomycetes and coryneform bacteria (Brennan, 1988).

The phospholipid and fatty acid composition are to a large extent dependent on the culture conditions. The growth temperature and the carbon source as well as the ratio of carbon and nitrogen sources affect the lipid composition (King and Perry, 1975; Dhariwal et al., 1977). Dhariwal et al. (1976) also reported the effect of culture age on the fatty acid composition. The major change they observed was an increase in tuberculostearic acid accompanied by a decrease in oleic acid (18:1) content. This composition is probably a reflection of the biosynthesis of tuberculostearic acid, which is formed by methylation of esterified oleic acid residues. This perhaps also explains why relatively high tuberculostearic acid contents have often been reported, as, very often, cultures were analyzed which were already in the stationary growth phase.

An important aspect which should be emphasized is that these studies were all performed with batch-grown cultures. This implies that the growth conditions and growth rates were rarely constant, thus making it difficult to ascribe the observed changes in fatty acid composition to a specific factor.

More reliable experimental data require the application of chemostat cultures. As discussed in the section on cultivation, the continuous culture of mycobacteria in chemostats has been demonstrated several times. Therefore the regulation of lipid composition, or indeed many other aspects of mycobacterial physiology, should be studied using chemostat cultures.

Iron Uptake

Mycobacterial iron metabolism, especially iron uptake, has been extensively studied by the group of Ratledge (Ratledge, 1982b; Ratledge, 1984). Mycobacteria appear to be unique in producing two different siderophores (exochelins and mycobactins), probably necessitated by the thick lipoidal nature of the cell envelope. Exochelins are extracellular siderophores, which until now have only been poorly characterized. Two types of exochelins, differing in their solubility in organic solvents, have been described (Ratledge, 1982b). The very hydrophobic mycobactins, which are located within the cell envelope, have been studied to a greater extent. The potential for using the mycobactin composition in the identification of rapidly growing mycobacteria (Hall and Ratledge, 1984) is discussed in the section on identification. Recent work has focused on the regulation of the biosynthesis of the different siderophores and other iron-regulated proteins (Sritharan and Ratledge, 1989). For *M.*

neoaurum, these components were coordinately expressed in the presence of low iron concentrations (<0.2 mg/liter). Increasing the iron concentration to 0.5 mg/liter (or more) resulted in repression of the synthesis of all three components (Sritharan and Ratledge, 1989).

Genetics

Our knowledge of the genetics and the molecular biology of mycobacteria lags behind that of thoroughly characterized species such as *Escherichia coli* or *Bacillus subtilis*. This is partly due to the low growth rate of mycobacteria but also to the ineffectiveness of many of the standard molecular biology techniques when applied to the mycobacteria. Recently, however, significant progress has been made, part of which has already been reviewed (Grange, 1982; Hopwood et al., 1988; Konicek et al., 1988).

Organization of Genetic Information

The estimated genome sizes of mycobacteria vary from 3 to 5.5×10^9 daltons (Baess and Mansa, 1978). As a comparison, the genome size of *E. coli* is 2.5×10^9 daltons. Mycobacterial DNA has a high G+C content (66–71 mol% for the strains examined by Baess and Mansa, 1978).

The presence of extrachromosomal DNA (plasmids) has been demonstrated conclusively in several species. Most of the strains studied were, however, slow-growing pathogens (Hopwood et al., 1988). Plasmids have also been described in fast-growing species although no selective markers could be attributed to them (Labidi et al., 1984). A 173-kb plasmid isolated from a *M. scrofulaceum* species (isolated from the environment) encoded mercury and copper resistance (Meissner and Falkinham, 1984; Erardi et al., 1987). This strain contained a total of four plasmids varying in size from 15 to 300 kb. Two smaller mycobacterial plasmids have been studied in more detail: Plasmid pLR7 (15.3 kb) from *M. intracellulare* has been mapped (Crawford and Bates, 1984), and the complete nucleotide sequence of pAL5000, a 4,837-bp plasmid from *M. fortuitum*, has been determined (Rauzier et al., 1988).

The organization and sequences of mycobacterial genes coding for ribosomal RNA (rRNA) have been studied quite intensively. The rRNA can be easily isolated and sequenced, and these sequences have potential as taxonomic markers (Cox and Katoch, 1986) and are used in determining phylogenetic relationships (Woese, 1987; also see Identification and Phylogeny and Taxonomy).

Using rRNA probes derived from *E. coli*, hybridization with DNA from *M. phlei* and *M.*

smegmatis revealed that these fast-growing strains contain two rRNA operons, whereas the slow-growing *M. tuberculosis* and *M. intracellulare* appeared to possess only one rRNA operon (Bercovier et al., 1986). The slow-growing *M. bovis* BCG also contains only one set of rRNA genes (Suzuki et al., 1987). It is tempting to speculate that the number of rRNA operons present in the genome forms the genetic basis for the difference in growth rate between the rapidly and slowly growing mycobacteria. *Escherichia coli* grows much faster than the fast-growing mycobacteria and possesses seven rRNA operons (Bercovier et al., 1986).

The rRNA genes of *M. smegmatis* have been studied by restriction analysis (Bercovier et al., 1989), and, like the *M. bovis* BCG rRNA genes (Suzuki et al., 1987), the genes coding for the different rRNAs are organized in operons in the order 16S—23S—5S, as in other eubacteria (Woese, 1987; Clark-Curtiss, 1990).

Genetic Recombination

Papers concerning the transfer of mycobacterial DNA through transduction and conjugation published in the 1970s have been reviewed (Grange, 1982; Konicek et al., 1988) and will not be discussed here. Genetic recombination of mycobacteria by spheroplast fusion to produce genetically modified strains for sterol transformation has also been reported (Jekkel et al., 1989).

However, other methods of genetic recombination are essential for a better genetic characterization of mycobacteria. Methods to efficiently transfer DNA between mycobacteria and *E. coli* and vice versa are consequently an important tool. The approach of Jacobs et al. (1987) to attack this problem was to construct a vector which replicates as a plasmid in *E. coli* and as a phage in mycobacteria. This was achieved by introducing an *E. coli* plasmid replicon into a nonessential region of mycobacteriophage TM4, a temperate phage of *M. avium*. The resulting "phasmid" phAE1 grows as a lytic phage in *M. smegmatis* and replicates as a plasmid in *E. coli*. DNA transfer into *M. smegmatis* was achieved by transfection of protoplasts, and introduction into *E. coli* was done by in vitro packaging with lambda proteins.

Subsequently, efforts were undertaken to use the same approach to construct lysogenic phasmids that would allow the introduction and maintenance of DNA in growing mycobacteria. "Shuttle phasmids" were constructed in a similar manner as described above using the temperate phage L1 which stably lysogenizes *M. smegmatis* by integrating in the chromosome (Snapper et al., 1988). With one of these phasmids (phAE19),

it was possible to lysogenize *M. smegmatis* protoplasts and generate kanamycin- and chloramphenicol-resistant colonies, thus illustrating the possibility of introducing and expressing foreign genes in mycobacteria (Snapper et al., 1988).

A much larger stimulation of research of mycobacterial genetics is expected from the construction of plasmids capable of replicating in both *E. coli* and mycobacteria. Snapper et al. (1988) have constructed such hybrid shuttle plasmids by randomly inserting the *E. coli* plasmid pIJ666, containing an origin of replication and the genes for kanamycin and chloramphenicol resistance in pAL5000 from *M. fortuitum*. Transformation of the pIJ666::pAL5000 library into *M. smegmatis* protoplasts was not successful. Subsequently the high voltage electroporation technique was applied. This method had previously been demonstrated to be useful in the transformation of other Gram-positive bacteria (Chassy and Flickinger, 1987). Electroporation conditions were optimized for the uptake of lytic D29 phage DNA by intact *M. smegmatis* cells, resulting in $>5 \times 10^3$ plaque-forming units per μg DNA. Electroporation of *M. smegmatis* using the optimized procedure with the pIJ666::pAL5000 recombinant library yielded 1–10 kanamycin-resistant transformants per μg DNA. Plasmids isolated from the transformants were used in retransformation experiments yielding kanamycin-resistant *E. coli* and *M. smegmatis* colonies.

Gicquel-Sanzey et al. (1989) used a similar approach to construct the 9.2-kb vector pAL8 by combining pAL5000 with an *E. coli* plasmid and a gene coding for kanamycin resistance. However, transformation of spheroplasts with the pAL8 vector was not successful using conditions under which transformation with the lytic mycobacteriophage D29 resulted in transformation efficiencies of 10^4 to 10^5 per μg DNA. Using the electroporation technique, Gicquel-Sanzey et al. (1989) reported transformation frequencies for *M. smegmatis* of 10 per μg pAL8 DNA. Electroporation of *M. smegmatis* with phage D29 resulted in transformation frequencies of 10^3 per μg DNA, similar to the rate reported by Snapper et al. (1988). Both groups report much higher transformation efficiencies (10^3 per μg DNA) for *M. bovis* BCG. Recently though, high-efficiency-transforming mutants of *M. smegmatis* have been isolated, yielding more than 10^5 transformants per μg DNA (Snapper et al., 1990b). Interestingly, these mutants do not show enhanced transformation frequencies with an integrating vector that recombines into the *M. smegmatis* chromosome. It is suggested that the mutation possibly affects plasmid replication and maintenance in *M. smegmatis*. Using these mutants, an essential replication region of pAL5000 was mapped and the gene coding for the 65-kDa

stress-protein antigen of *M. leprae* was expressed (Snapper et al., 1990a).

Deletion experiments with pAL8 have resulted in the construction of a smaller shuttle plasmid of 6.6 kb (pRR3) incorporating only 2.58 kb of pAL5000 (Ranes et al., 1990). The transformation rates of *M. bovis* BCG and a high-transforming mutant of *M. smegmatis* (Snapper et al., 1990b) using the electroporation technique with this plasmid were 10^4 per μg pRR3 DNA.

Transformation by electroporation of *M. aurum* and *M. smegmatis* with the broad-host-range, Gram-negative vector pJRD215 has also been demonstrated (Hermans et al., 1991). In contrast to the constructs described above, this cosmid vector does not contain mycobacterial DNA, i.e., a mycobacterial origin of replication. An advantage of pJRD215 is that it contains the phage lambda *cos* site, allowing the cloning of relatively large DNA fragments in *E. coli* and thereby facilitating the construction of genomic libraries. Expression of pJRD215 in mycobacteria should allow the screening of such libraries by the complementation of mutants. The kanamycin- and streptomycin-resistance genes carried by pJRD215 were both expressed in *M. aurum*. The transformation efficiency, as determined by screening for kanamycin resistance, was rather low at 2×10^2 transformants per μg DNA. Enhancement of the transformation frequency by pretreatment of the cells with isoniazid, as was demonstrated for the transformation of *M. aurum* with pAL8 (Hermans et al., 1990), might also be applied successfully for the transformation of mycobacteria with pJRD215.

Another approach to stably introduce DNA in mycobacteria, using a vector without a mycobacterial origin of replication, requires homologous recombination to take place. This was demonstrated with a shuttle vector that can replicate autonomously in *E. coli* but must integrate into homologous DNA for survival in *M. smegmatis* (Husson et al., 1990). The vector, pY6002, contained an *E. coli* origin of replication and the *pyrF* gene of *M. smegmatis* with the kanamycin-resistance gene *aph* as an insert. The *pyrF*-negative mutants are both uracil auxotrophic and fluorouracil resistant. The transformation frequency of *M. smegmatis* by electroporation with this vector was 10–500 transformants per μg DNA. Integration of pY6002 in the chromosomal DNA of the prototrophic “wild-type” *M. smegmatis* gave two types of kanamycin-resistant recombinants resulting from either a single or double recombination event. Class I recombinants resulting from a single recombination event contained the entire plasmid as well as a functional *pyrF* gene, whereas class II recombinants were uracil auxotrophic and fluorouracil

resistant. In class II recombinants, the plasmid had apparently integrated in the chromosome at the *pyrF* locus and replaced it. Class II transformants could be retransformed with a plasmid containing the intact *pyrF* gene without an *aph* insert (pY6001). Selection for uracil prototrophs gave both classes of transformants. Class I, resulting from a single recombination event, contained both the disrupted and the wild-type *pyrF* gene, while class II kanamycin-sensitive transformants only contained the wild-type *pyrF* gene. Using this technique, the 65-kDa stress-protein antigen of *M. leprae* was expressed in *M. smegmatis* at detectable levels. Two vectors were used with the *M. leprae* gene on a 3.6-kb fragment inserted at different sites of pY6002. The transformation frequencies were comparable to those of pY6002. The two transformants expressing the 65-kDa antigen were kanamycin resistant and fluorouracil sensitive, indicating them to be class I transformants (Husson et al., 1990).

The methods and tools allowing the transformation and molecular genetic manipulation of mycobacteria described above (Jacobs et al., 1987; Snapper et al., 1988; Snapper et al., 1990a; Husson et al., 1990; Hermans et al., 1991) should result in major advances in mycobacterial research in the near future.

Applications

The most obvious applications of mycobacteria are of course associated with the disease tuberculosis. Examples are the BCG (*Bacillus Calmette-Guérin*) vaccine, which is derived from the *Mycobacterium bovis* BCG strain, and the production of tuberculin, which is extracted from *Mycobacterium* cultures. Tuberculin is used diagnostically in a delayed hypersensitivity type of skin test for the detection of a current or previous infection with *M. tuberculosis*.

In this section we will focus on nonmedical applications. Mycobacteria are used mainly in the area of biocatalysis to perform specific transformation reactions. The justification for using microorganisms or enzymes for a particular transformation is usually the selectivity and specificity (regio- or stereospecificity) exhibited by the biocatalyst (Meijer et al., 1985).

One area in biotechnology that has a large number of commercial applications utilizing mycobacteria is the biotransformation of steroids. These processes involve either the modification of the steroid nucleus of natural or synthetic sterols or the selective degradation of the side chain of naturally occurring sterols such as cholesterol and β -sitosterol (Martin, 1984). The products formed can subsequently be chemically transformed to pharmacologically active

sterols (Martin, 1984). Cholesterol degradation by mycobacteria has been known for a long time (Söhngen, 1913) and usually involves simultaneous degradation of both the side chain and the steroid nucleus. Selective modification of only the nucleus or the side chain can be achieved by employing inhibitors in the biotransformation process or by using mutants (Martin, 1984). Wovcha et al. (1978) for example obtained *M. fortuitum* mutants blocked in various steps of sitosterol degradation. With these mutants, intermediates of the steroid-degradation pathway can be produced. Some of these intermediates can be used as substrates for the production of medically useful steroids. Most commercial processes for the selective side-chain cleavage of sterols employ mutant strains of *M. fortuitum* or *M. parafortuitum*, although other *Mycobacterium* species and bacteria of related genera are also used (Martin, 1984).

Many biocatalytic processes comprise only one enzymatic step, using enzyme preparations or whole (permeabilized) cells. An example is the utilization of *M. neoaurum* (ATCC 25795) containing an L-specific aminopeptidase with a very high stereospecificity and broad substrate specificity. Using permeabilized *M. neoaurum* cells, a wide range of L- or D- α -methyl-substituted amino acids can be produced by stereoselective hydrolysis of racemic mixtures of the corresponding amides (Kamphuis et al., 1987).

Another potential application of mycobacteria in the field of biocatalysis is the production of optically active epoxides from alkenes (Habets-Crützen et al., 1985b; Hartmans et al., 1989). Optically pure epoxides form versatile starting materials for the chemical synthesis of optically active pharmaceutical compounds. Screening a number of bacteria from different genera revealed that alkene-grown mycobacteria produce the epoxides examined (1,2-epoxypropane, 1,2-epoxybutane, and 2,3-epoxy-1-chloropropane) in the highest enantiomeric excess (Weijers et al., 1988). However, substantial research efforts will be required to increase the specific activity and the operational stability of the biocatalysts before commercial production of epoxides by the alkene-utilizing mycobacteria can be realized. In this respect, product toxicity and cofactor regeneration have been studied for the production of 1,2-epoxypropane with the ethene-utilizing *Mycobacterium* strain E3 (Habets-Crützen and De Bont, 1985a; Habets-Crützen and De Bont, 1987).

One aspect that has received some attention is the use of organic solvents and immobilization of mycobacteria for application in continuously operated processes (Steinert et al., 1986; Flygare and Larsson, 1987). The advantages of immobilization (i.e., increased reactor productivity or a

better operational stability) were however not very evident. One advantage that immobilization of cells can offer is that organic solvents, which can function as a reservoir for substrates and products with a low water solubility, can be used without the problems of cell aggregation and biocatalyst/solvent separation associated with the use of organic solvents with free cells (Linko and Linko, 1985). However, immobilization does not protect the cells against the adverse effects many solvents have on mycobacteria (Brink and Tramper, 1985; Steinert et al., 1986). In the study of Brink and Tramper (1985), complete retention of activity was observed in the presence of dioctyl and didecyl phthalate, but most solvents resulted in decreased biocatalytic activity.

The effect of water-immiscible organic solvents on growth has also been tested with the rapidly growing strain *Mycobacterium* E3 and several other bacteria from different genera (Rezessy-Szabó et al., 1986). From these experiments, *Mycobacterium* E3 was not particularly resistant to organic solvents compared to other bacteria, as for instance *Pseudomonas* species.

Another area of research concerning the potential application of mycobacteria is in environmental biotechnology. Removal of traces of the plant hormone ethene from storage facilities for fruit using immobilized ethene-utilizing mycobacteria is one example (Van Ginkel et al., 1986). Unfortunately, the activity of the ethene-utilizing mycobacteria was very low at the ethene levels (often less than 1 part per million [ppm]) prevailing in the fruit storage facilities. Another example is the application of the vinyl chloride-utilizing *Mycobacterium* strain L1 to remove the carcinogenic vinyl chloride from industrial waste gases (Hartmans and De Bont, 1992). The compound is metabolized by an initial oxidation step to the corresponding epoxide by alkene monooxygenase. Accumulation even of very low concentrations of this reactive intermediate, which can occur because of fluctuations in the vinyl chloride supply, irreversibly inhibited the alkene monooxygenase. As such fluctuations will probably frequently occur, practical application of this strain does not seem realistic.

The use of mycobacteria in the bioremediation of contaminated sediments has also been suggested. Addition of a pyrene-degrading *Mycobacterium* strain to sediments resulted in an enhancement of the mineralization rates of several polycyclic aromatic hydrocarbons. Further investigations were suggested to assess the potential of this strain in the bioremediation of contaminated sediments (Heitkamp and Cerniglia, 1989).

A disadvantage of mycobacteria in general is their relatively low growth rate and hence their low catalytic activities. However, mycobacteria

are likely to play an increasingly important role as a source of interesting biocatalytic capacities now that the development of the molecular genetic tools required to increase the expression of desired activities, either in mycobacteria or other hosts, is well under way.

The Genus *Mycobacterium*—Medical

BEATRICE SAVIOLA AND WILLIAM BISHAI

Introduction

The genus *Mycobacterium* encompasses a number of medically important species that exact an alarming toll in human morbidity and mortality. Indeed the World Health Organization (WHO) estimates that nearly one third of the world's population (1.8 billion people) are infected with *Mycobacterium tuberculosis*, the cause of tuberculosis (TB) (<http://www.who.org>). In 1993, the WHO declared a global emergency owing to the fact that TB was epidemic in many areas of the world. Other mycobacterial diseases continue to plague the world's populations as well. *Mycobacterium leprae*, the cause of leprosy, persists in developing countries, and other mycobacteria (ordinarily nonpathogens) have now become threats to individuals infected with the human immunodeficiency virus (HIV).

Mycobacteria have shaped the course of human history. Indeed until 1900, TB was one of the chief causes of death in Europe and the Americas. The nature of the disease, however, remained poorly understood and as a testimonial to this fact its contagiousness was the subject of heated debate well into the 18th and 19th centuries. For many years, psychological and inherited factors were thought to predispose individuals to the disease. However, others thought that a contagious agent was the culprit. This debate ended only after the bacillus *Mycobacterium tuberculosis* was identified as the causative agent of TB. Jean Antoine Villemin in 1868 was the first to transmit TB from man to rabbit (Haas and Haas, 1996). As a military doctor, he had observed that many young healthy military personnel housed in barracks eventually succumbed to TB. He also noted that a disproportionate number of individuals with active TB were prisoners, industrial workers, members of cloistered religious orders as well as military personnel; all of them were housed together with many other people. Villemin speculated that TB was transmissible. He used material (gray and soft tubercles) from humans who had succumbed to TB as well as blood and sputum from tuberculous patients to infect rabbits. The inoculated rabbits indeed

developed pathologic evidence of tuberculosis. Then in 1882, Robert Koch was the first to view *Mycobacterium tuberculosis* through a light microscope. He was then able to grow *M. tuberculosis* in pure culture, infect guinea pigs with the bacilli, and reisolate bacteria from these animals (Adler and Rose, 1996). Thus a new era of mycobacteria research was born.

In Europe and the United States, a sanatorium movement was underway by the 1890s to isolate and cure those patients having TB. Edward Livingston Trudeau started one of the first and most successful of the sanatoria in the United States (Davis, 1996). After providing hospice care for his consumptive brother, Dr. Trudeau was stricken with that same disease. He fled to the Adirondack Mountains believing that fresh air, nutritious food and exercise would restore his health. As hoped, his disease symptoms abated and his health consequently improved. He chose to move permanently to Saranac Lake in the Adirondack Mountains where he bought land, built cottages and started the Adirondack Cottage Sanatorium. Dr. Trudeau immersed himself in research and succeeded in cultivating pure *Mycobacterium tuberculosis*, which he provided to other researchers. Out of the Saranac Lake Laboratory, the Trudeau Institute (<http://www.trudeauinstitute.org>) for biomedical research was born in 1954. Not until the development of successful antimycobacterial chemotherapy did this and other sanatoria lose their function and close their doors to the public.

In 1944 streptomycin was isolated and identified by Dr. Selman Waksman and his graduate student Albert Schatz (Harris, 1996). It marked the first drug in a line of antibiotics having antimycobacterial properties. In 1952 isonicotinic acid hydrazide (INH) was found to have antimycobacterial properties as well and has since become a mainstay in the antibiotic therapy of TB. With the advent of these new advances in the chemotherapy of TB, victory was declared over the disease; however, this declaration would prove premature. Following an extensive period of decline, the incidence of TB in the United States began to rise again in the late 1980s. The

HIV epidemic combined with an urban drug problem provided fertile ground on which *M. tuberculosis* could flourish anew. Concomitant with this alarming trend was detection of an increasing incidence of drug-resistant *M. tuberculosis*. To combat these problems, the WHO as well as government agencies in countries around the world have increased spending in both the public health forum as well as biomedical research. Today, research on *M. tuberculosis* as well as other members of the genus is providing valuable insight into the basic biology of mycobacterial survival and replication inside the host. Lessons learned through these studies will hopefully provide novel treatments to combat the renewed threat of this age-old enemy.

Taxonomy

The genus *Mycobacterium* comprises a number of Gram-positive aerobic bacteria and is the only member of the family Mycobacteriaceae within the order Actinomycetales. The genus shares an unusually high genomic DNA G+C content (62–70%) and the production of mycolic acids with closely related genera, *Nocardia* and *Corynebacterium*, within Actinomycetales. Phylogenetic trees are available which depict genetic relatedness based on homology of the 16S ribosomal gene sequence. Mycobacteria that have highly homologous rRNA sequences are closely related and are on neighboring branches of the tree (Fig. 1). The mycobacterial phylogenetic tree can be further subdivided into fast and slow growing bacteria. The fast growers form colonies on selective media in less than 7 days and the slow growers, in greater than 7 days. In addition, within the genus *Mycobacterium* a number of species are grouped into complexes (e.g., *M. avium* and *M. tuberculosis* complexes) that include bacterial species that have a high degree of genetic similarity as well as cause similar disease syndromes.

Habitat

Mycobacterium tuberculosis is an obligate pathogen of humans and is rarely identified in other mammals. It is transmitted from person to person, and it has no significant environmental reservoirs. *Mycobacterium bovis*, which causes tuberculosis in humans and in cattle, has a natural reservoir in ruminants. As a consequence, foodstuffs (including cheese and milk originating from these animals) were often contaminated prior to the introduction of current pasteurization and meat inspection procedures. A number of other medically important mycobacteria are found in the environment. Water serves as the

habitat for a number of mycobacterial species including *M. marinum*, *M. chelonae*, *M. fortuitum*, *M. kansasii* and *M. avium*. Although not yet confirmed, stagnant water may be a habitat for *M. ulcerans*. Soil may also harbor mycobacteria including *M. chelonae*, *M. fortuitum*, and *M. avium*.

Isolation

Medically important mycobacterial species can be isolated and cultured from a number of environmental sources; however, *M. tuberculosis* is rarely isolated from nonhuman sources. As pulmonary tuberculosis is the most frequent form of the disease, sputum is the most common body specimen submitted for culture—although blood, gastric aspirates and biopsy specimens may also be analyzed.

Before sputum samples from patients may be tested for mycobacterial growth, they must be decontaminated to remove rapidly growing upper respiratory flora. Decontamination procedures take advantage of the thick lipid envelope of mycobacteria and this organism's natural resistance to chemical agents. *N*-Acetyl-L-cysteine (0.5–2.0%; NALC) liquefies sputum samples. The compound has minor inhibitory effects on mycobacteria but does allow other antibacterial agents to access and neutralize contaminating organisms. Sodium hydroxide is used to inactivate contaminating bacteria with only modest inhibitory effects against mycobacteria.

Once decontaminated, samples may be used to inoculate either a solid or liquid growth medium. The solid growth media are available as either egg- or agar-based. Both types of solid media contain malachite green dye, which inhibits the growth of many other bacteria. The commonly used Löwenstein-Jensen (LJ) medium is egg-based (Fig. 2), whereas Middlebrook 7H10 and 7H11 are agar-based media. Growth can also be assayed in a liquid medium such as Middlebrook 7H9; however, these media are more problematic because overgrowth by contaminating bacteria is more difficult to detect.

Growth of mycobacteria from clinical specimens is time-consuming because there is often a lag of three to four weeks before sufficient growth is achieved. To shorten growth detection times, the Bactec (Becton-Dickinson) system may be used (Fig. 2). Mycobacteria are grown in 7H9 that contains ^{14}C -labeled palmitic acid as a carbon source. As the bacteria grow they catabolize the radiolabeled carbon source and convert it to gaseous $^{14}\text{CO}_2$. A specially designed instrument (Becton Dickinson) samples the amount of ^{14}C above the mycobacterial cultures and converts this information into an index of growth.

Fig. 1. A phylogenetic tree based on 16S rRNA sequences of the genus *Mycobacterium* depicts closely related species on neighboring branches. Redrawn from Shinnick and Good (1994).

The Bactec method reduces detection time in liquid media to 9–14 days for *M. tuberculosis* (Middleton et al., 1997; Pfyffer et al., 1997). Recently a completely closed system called the mycobacterial growth indicator tube (MGIT) system has been introduced. The tube contains a plastic resin that fluoresces as oxygen levels are depleted by growing bacteria, and an automated fluorescence detector reports growth readings at

regular intervals (Saito et al., 1996; Sharp et al., 1996).

Identification

Once mycobacteria have been isolated from either an environmental or a human source, the speciation process can begin. Acid-fast staining

Fig. 2. The growth medium Löwenstein Jensen (left) is used to culture mycobacteria. *Mycobacterium tuberculosis* takes 3 to 4 weeks to produce colonies on this growth medium. The Bactec 12B (right) bottle is used for radiometric detection of mycobacterial growth. Early growth of mycobacteria is detected by the conversion of ^{14}C -labeled palmitate to gaseous ^{14}C -labeled CO_2 . An automated sampling needle removes a small amount of gas through a rubber septum each day, and a detector measures the radioactivity obtained. Using the Bactec system, mycobacterial growth may be detected in 7–15 days.

in combination with light microscopy permits an initial rapid diagnosis of a mycobacteriosis. Mycobacteria are acid fast by nature. They form stable complexes with arylmethane dyes such as fuchsin and auramine O. The phenol used in the primary staining procedure allows the stain to penetrate. The mycolic acids in the cell wall act to retain the stain even after the exposure to acid alcohol or strong mineral acids. The resulting acid-fast mycobacteria can be identified microscopically. The Ziehl-Neelsen and Kinyoun methods are acid stains in which the acid-fast bacilli (AFB) appear red against a blue or green background (Fig. 3). Fluorochrome-staining procedures can be used as well. In these procedures, which use auramine O or auramine-rhodamine, the AFB fluoresce yellow to orange. Fluorescence staining is superior as AFB are more easily identified at a lower magnification. Initial microscopic identification of bacteria, while rapid, is not reliable, has a sensitivity that ranges from 22 to 80%, and does not allow species identification of AFB. Therefore, other methods of mycobacterial identification are necessary (Nolte and Metchock, 1995).

A host of biochemical tests can be used to differentiate mycobacterial species. Biochemical tests that distinguish *M. tuberculosis* from other species include the niacin accumulation test, the 68°C catalase test and the nitrate reduction test

Fig. 3. Kinyoun acid-fast stain of *Mycobacterium smegmatis*. Bacilli appear as small red rods with clumping.

(Kent and Kubica, 1985; Nolte and Metchock, 1995). Because *M. tuberculosis* has a blocked pathway for the conversion of free niacin to nicotinic acid mononucleotide, the bacterium accumulates niacin and excretes it into the culture medium. As confirmation, additional biochemical tests (e.g., the nitrate reduction test) must be performed inasmuch as strains of some mycobacterial species other than *M. tuberculosis* also accumulate niacin. *Mycobacterium tuberculosis* is a strongly positive nitrate reducer. Because *M. kansasii*, *M. szulgai* and *M. fortuitum* also reduce nitrate, an additional test (e.g., heat-stable catalase) should be used. The heat-stable catalase test assays the amount of catalase present in the bacterium after it has been resuspended in a buffer and heated to 68°C. *Mycobacterium tuberculosis* always loses its catalase activity under these conditions.

Once AFB have been observed in culture, most clinical labs use a nucleic acid hybridization test rather than the more laborious biochemical tests to speciate the isolate. The Accuprobe assay is available through Gen-Probe (<http://www.gen-probe.com>). This assay uses the Hybridization Protection Assay (HPA) where a DNA acridinium-ester-labeled probe hybridizes to a mycobacterial rRNA target sequence. A selection agent cleaves the label away from the unhybridized probe but leaves untouched the probe that is complexed with its target sequence. Light (detected with a luminometer) will be emitted from the DNA probe that is complexed to the rRNA. The advantage of this technique is that it can identify small quantities of mycobacteria due to the many copies of the rRNA target sequence in each mycobacterium. Thus there is an inherent amplification of the signal sequence. Gen-Probe has available probes that are specific for *M. avium*, *M. intracellulare*, the *M. avium*

complex, *M. gordonae*, *M. kansasii* and the *M. tuberculosis* complex.

Nucleic Acid Amplification Tests to Detect and Speciate *M. tuberculosis* Directly from Sputum

Even shorter detection times may be achieved using various commercially available nucleic acid amplification assays (NAA) designed to work using sputum. The United States Food and Drug Administration (USFDA) has approved several commercially available amplification tests for use directly with sputum. These tests include the *Mycobacterium tuberculosis* Direct Test from Gene-Probe (MTD; <http://www.gen-probe.com>) and the Amplicor (<http://www. Roche.com/diagnostics/>) *Mycobacterium tuberculosis* (MTB) Test. The MTD combines Transcription Mediated Amplification, which can amplify target rRNA sequences, with the HPA described in the previous section. This test is approved by the USFDA for use with sputum samples that are both positive and negative for AFB. The MTB test uses the polymerase chain reaction (PCR) to amplify DNA specific to *M. tuberculosis*. This test is approved by the USFDA for use with sputum samples positive for AFB. The LCx *M. tuberculosis* Test (<http://www.abbott.com/research/diagnostics.htm>) (Abbott) utilizes a ligase chain reaction where two oligos are hybridized to a target sequence from the mycobacteria and are subsequently ligated. The ligated oligos then serve as templates for additional oligos to hybridize and be ligated, resulting in amplification of the target sequence. At present this test is not approved for use with sputum within the United States. A recent study comparing two NAA methods revealed that MTD and LCx had sensitivities of 98.6 and 100%, respectively, and specificities of 99.4 and 99.3% with smear-positive samples (Wang and Tay, 1999). The Amplicor MTB test was analyzed in clinical trials and had a sensitivity of 95.0% and a specificity of 100% with smear-positive sputum samples (Amplicor, 2000). The NAA tests, while costly, are slightly more sensitive than acid-fast staining procedures. These tests hasten care for infected individuals by quickly identifying mycobacteria within about 25–50% of sputum samples that are negative by acid-fast staining but later culture positive. This aspect of the NAA tests is important especially in view of the recent evidence supporting the transmission of *M. tuberculosis* from patients who did not have acid-fast bacilli in their sputum (Behr et al., 1999). Additionally, in contrast to acid-fast staining, NAA tests provide information about species present within a

sputum sample. Thus, *M. tuberculosis*-infected individuals can be isolated and treated more rapidly, preventing the spread of the bacteria. The NAA tests cannot differentiate live from dead bacteria and therefore may not prove helpful for monitoring response to therapy.

Once a bacterial isolate has been identified as *M. tuberculosis*, it can be further subtyped to the strain level. The ability to differentiate *M. tuberculosis* on the strain level has enhanced our knowledge of the epidemiology of TB. In fact it has led to the identification of large outbreaks of disease traced back to a single person (Edlin et al., 1992; Valway et al., 1998). Strain typing also has led to the discovery of unsuspected routes of transmission such as medical equipment (Agerton et al., 1997; Michele et al., 1997), embalming (Sterling et al., 2000), or exposure to childhood TB (Curtis et al., 1999). It has been used, as well, to assess the amount of recent transmission of *M. tuberculosis* in the community, thereby redefining our understanding of the balance between primary active and reactivation TB after a period of latency. Techniques of DNA fingerprinting allow the identification of different *M. tuberculosis* strains. Virtually all *M. tuberculosis* strains have 1–26 copies of an insertion sequence IS6110. When a strain's chromosomal DNA is fragmented with restriction enzymes, the number of copies and location of these insertion sequences within the chromosome produce a restriction length polymorphism (RFLP) pattern that characterizes the strain. In addition, the frequency with which IS6110 moves within the chromosome is low enough to allow identification of specific strains that are the cause of an outbreak. Reasonable identification of a strain can be obtained when the bacterium contains six or more IS6110 elements. In the event that a strain contains less than six insertion elements, a second probe may be used for increased specificity. This second probe is generally for the polymorphic GC-rich repetitive sequence (PGRS). Distinct strains will have a unique pattern of probe hybridization, thus facilitating identification (Harrington and Bishai, 2000).

Current research in diagnostics for TB is focusing on techniques that are fast, sensitive and specific. A major challenge is to develop inexpensive tests, which may be used in developing countries where TB is abundant. These tests could potentially identify patients with active TB early, thus permitting the isolation of such individuals and preventing the spread of the bacilli. Earlier identification of those individuals that harbor *M. tuberculosis* could possibly lower TB rates in many parts of the developing world.

Physiology

Mycobacteria are straight or slightly curved non-motile rods (approximately 0.2–0.6 μm wide by 1.0–10 μm long; Fig. 4), aerobic, nonsporeformers that grow at times as filaments. Two remarkable bacteriologic features define mycobacteria. First, they have a cell wall that is rich in long-chain fatty acid esters known as “mycolic acids” that are attached to the cell wall through arabinogalactan (Fig. 5). Mycolic acids are chemically related to wax and give the colonies their characteristic waxy appearance and the cells a tendency to clump and resist dispersion. The waxy nature of the coat renders the bacteria not readily stainable (such as by the Gram method) with aniline dyes, though the bacteria are considered to be Gram positive. Mycobacterial mycolic acids do, however, form strong complexes with some dyes that leave them resistant to decolorization with acid alcohol. Therefore the identification of AFB in a sample is suggestive of

mycobacteria (Fig. 3). In addition, this lipid coat renders the mycobacteria impervious to many aseptic solutions and antibiotics. Second, all mycobacteria grow slowly with generation times

Fig. 4. *Mycobacterium smegmatis* colony morphology after three days of growth from a single bacterium.

Fig. 5. Schematic representation of the plasma membrane and outer wall of *Mycobacterium tuberculosis* reveals an abundance of mycolic acids. Phosphatidyl-inositol mannosides (PIMs), lipoarabinomannans (LAMs) and lipomannan (LM) portion of LAM are shown as outer wall constituents. From Brennan and Nikaido (1995).

that range from 2 hours for *M. smegmatis* to 12 days for *M. leprae*.

Genetics

The Completed *Mycobacterium tuberculosis* Genome

Genetic research into the virulent nature of *M. tuberculosis* has long been hampered by the organism's slow growth. The generation time of *M. tuberculosis* is 24 hours in contrast to the 20-minute generation time of the common laboratory bacterium *Escherichia coli*. The tendency for mycobacteria to form clumps also leads to significant technical challenges in the research laboratory. As a consequence, traditional genetic screens and selections are difficult to conduct. Therefore, reverse genetic approaches have been emphasized in the study of *M. tuberculosis*. This technique targets specific proteins homologous to proteins of known function and importance in other organisms for study at a molecular level within a host. As a result, the elucidation and analysis of the whole genome sequence of *M. tuberculosis* have become increasingly important.

In 1998, the complete genome sequence of the *M. tuberculosis* strain H37Rv was elucidated (Cole et al., 1998). The completion of the genome sequence was a collaborative effort of the Wellcome Trust and the Institute Pasteur. A web site at the Institute Pasteur shows the completed genome. In addition, The Sanger Center maintains a web site where DNA segments and predicted proteins from the *M. tuberculosis* strain H37Rv may be compared to peptides and DNA from other organisms. The Institute for Genomic Research (TIGR) has completed the sequence for another *M. tuberculosis* strain, CDC1551 (CSU93). At the TIGR web site, one may also compare the chromosomal sequence to other known genes and predicted proteins. In addition, The National Center for Biotechnology Information offers a web site where the *M. tuberculosis* genome may be accessed and the chromosomal sequence may be visualized on a map.

The genome sequence is 4.4 Mbp. Researchers now have at their disposal the information defining every possible drug target, antigen for incorporation into a vaccine, as well as every virulence determinant from *M. tuberculosis*. Annotation of the H37Rv sequence reveals 3,924 open reading frames (Cole et al., 1998). The genome has no easily identifiable pathogenicity islands as other organisms have. However, many repetitive elements were identified, including IS6110, which have been used as a tool to identify varying

strains during outbreaks of *M. tuberculosis* (Harrington and Bishai, 2000). The mycobacterium contains within its repertoire genes that could allow the bacterium to adapt to a range of environmental conditions, from growth in a rich broth to survival in host macrophages. These genes include 13 putative σ factors, 140 transcriptional regulators, 32 component regulators that presumably sense environmental signals, and 14 protein kinases or phosphatases. The genome also possesses 250 genes involved in a complex lipid metabolism, which the cell needs to synthesize material for its waxy coat (Cole et al., 1998). Several new classes of putative proteins termed "PE" and "PPE" (each with internal repetitive sequences) were also identified in the genome sequence. Indeed, ten percent of the genome is composed of these new potential coding sequences. The PE or PPE class of proteins has been proposed to be involved in modulation of the host immune response (Cole et al., 1998).

Epidemiology

Tuberculosis causes more deaths than any other infectious organism; 6 million new active cases and 3 million deaths annually are attributed to *M. tuberculosis*. Indeed, rates of TB in the world are predicted to increase 50% each decade. However, the annual incidence of TB in the United States remains low with 8.7 cases/100,000 people. Prior to 1985, TB rates within the United States were steadily declining at approximately 6% per year. In striking contrast to this trend, from 1986 to 1992 the incidence of TB cases rose about 3% per year (Fig. 6). A

Fig. 6. After many years of decline, reported TB cases in the United States began to rise in the late 1980s. Following public health intervention, TB cases are once again dropping CDC.

maximum of 26,673 cases occurred in 1992. Increased government funding for public health programs and increased use of directly observed therapy (DOT) for tuberculosis have decreased rates since 1992 (Chaisson and Bishai, 1997). As a result, in 1998 the United States Centers for Disease Control and Prevention (CDC) reported 18,361 cases. Again, in 1999 the incidence of new TB cases fell to 17,528 cases.

Despite the fact that the number of cases in the United States is now dropping, there is the new problem of multidrug-resistant TB. The term multidrug-resistant tuberculosis (MDRTB) is used to describe strains that are resistant to two or more of the five first-line anti-TB drugs: isoniazid, rifampin, pyrazinamide, ethambutol and streptomycin. Indeed the incidence of drug resistance has increased in urban settings and among HIV-infected populations. In fact, during 1991, 33% of all TB strains recovered in New York City were MDRTB. The United States rate of MDRTB, however, has now fallen with improved control measures, but the global problem of drug resistance continues. In an international survey between 1994 and 1997, 12% of incident cases were resistant to at least one drug and 7.6% of TB strains were resistant to isoniazid (Pablos-Mendez et al., 1998).

Risk factors for TB include intravenous drug abuse, alcoholism, chronic pulmonary disease, prolonged steroid use, diabetes, renal failure, malnutrition and organ transplant. Infection with HIV is also a risk factor for TB: HIV-infected patients have a 25–50 fold increased risk compared with HIV-negative individuals. A number of social factors also increase a person's risk of TB including institutional living, urban dwellings, poverty and low educational levels (Chaisson and Bishai, 1997).

The incidence of other mycobacterial diseases has increased in recent years. Diseases caused by the *Mycobacterium avium* complex (MAC) were uncommon prior to the AIDS epidemic. Infection with MAC was mostly seen in individuals that were immunocompromised or had underlying lung disease. Indeed, prior to 1981 the incidence of MAC cervical lymphadenitis and MAC pulmonary infection was approximately 300 and 3,000 cases per year, respectively, in the United States. With the onset of the AIDS epidemic, the incidence of disseminated MAC infection jumped in the mid-1990s to approximately 20,000 individuals per year (Chaisson and Bishai, 1997). The MAC rates, however, appear to have peaked in 1997 and have since fallen due to improved antiretroviral therapy for patients infected with HIV (Palella et al., 1998).

Disease

THE *MYCOBACTERIUM TUBERCULOSIS* COMPLEX The *M. tuberculosis* complex is comprised of *M. tuberculosis*, *M. bovis*, *M. microti* and *M. africanum*. Only *M. tuberculosis* and *M. bovis* are a significant source of human disease (<http://www.hopkins-tb.org>). *Mycobacterium microti* causes disease in voles and was employed as a vaccine in the earlier part of the twentieth century (Wells and Oxon, 1937; Birkhaug, 1946; Wells, 1949; Wells and Wylie, 1954). *Mycobacterium africanum* causes disease in humans but makes up only a minority of cases of pulmonary TB, and its incidence is isolated to Africa.

M. TUBERCULOSIS The main route of infection of *M. tuberculosis* is by person-to-person inhalation of infectious aerosols. Bacilli are transmitted through speaking, coughing, sneezing and singing. Droplets of infectious *M. tuberculosis* are sized in the range of 1–10 μm . After inhalation of the droplets, the bacteria travel to the terminal bronchioles and alveoli where they are phagocytosed by alveolar macrophages. Many of these bacilli are killed in the phagosomes after these fuse with lysosomes and become acidified. *Mycobacterium tuberculosis*, however, is an intracellular pathogen and can efficiently inhibit phagosome-lysosome fusion (Fig. 7). As a result some of the invading *M. tuberculosis* bacilli survive these initial host defenses. Surviving bacilli grow within the macrophages and are released when the macrophages die. Unactivated macrophages arrive from the blood stream and ingest the newly liberated bacilli, which grow symbiotically within the unactivated macrophages for approximately 3 weeks. Eventually the bacilli lyse the macrophages and spill out into the host tissue.

Fig. 7. Macrophages infected with *M. bovis* BCG are visualized by acid-fast staining. Mycobacteria are small red rods within the blue-stained macrophages.

Fig. 8. Cavitory pulmonary tuberculosis in a 36-year old man. Right upper lobe streaky infiltrates and nodules are seen; two cavities are also present near the right apex.

In resistant individuals, released bacterial products stimulate strong cell-mediated immunity through Th1 signaling with INF- γ , IL-2, and IL-12. Activated macrophages that can kill *M. tuberculosis*, as well as T cells, are recruited to the periphery of the infectious focus. The bacteria and cellular debris are contained in a tissue structure called “a caseous granuloma.” The disease will be halted at the stage where this small granuloma is formed.

In sensitive individuals, cell-mediated immunity is weak, and bacilli continue to multiply. Macrophages arrive to engulf the bacilli while T cells also accumulate. Because the macrophages are inadequately activated, the *M. tuberculosis* bacilli also parasitize the recruited macrophages. Cytotoxic T-cells produce toxic substances, which results in damage of host tissues. This cycle is repeated so that the granuloma enlarges. Eventually, tissue damage may result in cavity formation within the lung as well as in liquefaction of the granuloma (Figs. 8 and 9). *Mycobacterium tuberculosis* bacilli are particularly adept at multiplying in a liquefied cavity from which they are then expelled and spread through coughing and sneezing (Dannenberg, 1993; Dannenberg, 1994).

As they have no environmental reservoirs, *M. tuberculosis* organisms spread from person to person. In addition, fomites are not thought to support the transmission of the disease. Some (25–50%) of the diseased individual’s close contacts will become infected with *M. tuberculosis*. However, only a minority (5% of those exposed) is susceptible and will develop primary active disease. In contrast, most humans seem to be naturally resistant to *M. tuberculosis*; these indi-

Fig. 9. Lung of a rabbit infected with *M. bovis*. Cavities are abundant within the lung.

viduals harbor the bacilli and develop only a latent infection. Approximately 95% of infected individuals control the spread of *M. tuberculosis* within the body and disease progression is halted at the stage where a small granuloma is formed. These individuals may have a lifelong latent infection with no symptom other than a positive reaction to the administration of purified protein derivative (PPD) of *M. tuberculosis*, indicating immune memory of *M. tuberculosis* infection. Any process that disrupts the immunocompetence of a latently infected individual, however, may cause active infection to develop. The elderly often have a recrudescence of disease after decades of a latent infection due to their waning immunity. Acquiring a viral infection such as HIV may cause an individual to become immunosuppressed and develop active from latent disease. In fact, HIV-infected individuals have a 4–8% yearly risk for reactivation TB whereas immunocompetent individuals have only a 5–10% lifetime risk (Chaisson and Bishai, 1997).

Disease development due to *M. tuberculosis* infection can be either pulmonary or extrapulmonary. Inasmuch as infection is mainly through the aerosol route, immunocompetent individuals manifest primarily pulmonary disease. Symptoms include cough, chest pain, sputum production, fever, night sweats and hemoptysis in advanced disease. About 15% of TB cases in immunocompetent individuals occur at extrapulmonary sites. Such cases are attributed to reactivation of a latent extrapulmonary focus of infection, because during the initial infection

process transient bacteremia may occur. Occasionally hospital and laboratory workers infect soft tissues through accidental injection with *M. tuberculosis*-contaminated syringes. In those cases infection is extrapulmonary but may spread by the blood to the lungs and other organs if the immune system cannot check the growth of the bacilli. Immunocompromised individuals (such as the very young, old and those infected with HIV) are more likely to develop extrapulmonary tuberculosis.

M. BOVIS Isolated from cattle, *M. bovis* causes TB in ruminants and occasionally humans. This organism prefers to grow at 37°C and growth of a colony from a single bacillus usually requires 3–4 weeks of culture. Before routine pasteurization was practiced, humans could be infected by drinking *M. bovis*-contaminated milk. In fact milk was an important reservoir of infectious bacilli. However, since pasteurization became commonplace in the United States and in much of the world, the incidence of *M. bovis* infection has decreased considerably. *Mycobacterium bovis* is spread among cattle by an aerosol route and from cattle to humans by either a gastrointestinal or an aerosol route. In humans, *M. bovis* may cause intra-abdominal TB, cervical lymphadenitis (scrofula) or pulmonary TB (Adler and Rose, 1996). *Mycobacterium bovis* was used to derive the well-known attenuated vaccine strain, bacille Calmette Guérin (BCG), which is still used in many parts of the world.

M. AFRICANUM This slow growing mycobacterium, first described in 1969, is infrequently associated with human pulmonary disease. It causes a disease similar to that caused by *M. tuberculosis* and *M. bovis*. Most patients with this disease reside or have resided in Africa. *Mycobacterium africanum* probably spreads by an aerosol route (Adler and Rose, 1996).

THE *MYCOBACTERIUM AVIUM* COMPLEX The *M. avium* complex is comprised of three species, *M. avium*, *M. intracellulare* and *M. paratuberculosis*. All three species are common in the environment, as they are isolated from soil, water, food and domestic animals. Categorized as slow growing mycobacteria, these species grow optimally at 37°C and achieve growth in approximately 4–6 weeks (Havlir and Ellner, 2000). Colonies are nonpigmented and are both opaque and domed or flat and transparent (Toosi and Ellner, 1998). *Mycobacterium avium* causes a tuberculosis-like infection in chickens, pigeons and other birds, whereas *M. paratuberculosis* causes Johne's disease in ruminants, which is a contagious enteritis resulting in progressive wasting and eventual death (Fraser et al., 1986). *Mycobacterium*

paratuberculosis has not been shown to cause human disease.

In humans, *M. avium* and *M. intracellulare* can cause pulmonary disease, regional lymphadenitis or disseminated disease. Those individuals who are coinfectd with HIV are prone to disseminated disease, whereas those who are not coinfectd are likely to have pulmonary disease. Predisposing factors to infection with *M. avium* include underlying lung disease, HIV infection, chronic obstructive pulmonary disease, chronic bronchitis, healed or active TB, pulmonary mycosis and malignancy. Infection occurs by either inhalation or ingestion of the infectious bacilli. Diagnosis in those affected individuals without HIV is made by radiographic evidence of disease, positive sputum cultures and an acid-fast smear. Symptoms are a productive cough, hemoptysis, fever and weight loss (Chaisson and Bishai, 1997).

Disseminated *M. avium* is a late opportunistic infection in those individuals coinfectd with HIV. In fact, disseminated MAC generally occurs only in AIDS patients with CD4 cell counts less than 100/mm³ (Chaisson and Bishai, 1997). Symptoms of infection are fever, drenching night sweats and weight loss. The hallmark of a disseminated infection is the high circulating levels of MAC bacteremia, which can reach 10⁴ bacteria/ml. Organ involvement may be widespread and the tissue burden may reach 10⁶ bacteria/g. The gastrointestinal tract is frequently infected, leading to symptoms including nausea, vomiting, watery diarrhea and abdominal pain. Left untreated, the disease will cause progressive clinical deterioration (Havlir and Ellner, 2000).

MYCOBACTERIUM LEPRAE Leprosy is particularly dreaded because it may cause bodily deformities leading to social stigmatization. In centuries past, persons suffering from leprosy were ostracized and forced to live away from the general population, in colonies or leprosaria. Today many patients suffering from leprosy are still concerned about the social stigma associated with leprosy. As of 1999, there were 719,332 leprosy cases registered for treatment. Almost all of these individuals were receiving multidrug therapy. The new case detection rate stayed the same or was increasing with 747,369 new cases detected during 1998 (<http://www.who.int/lep>). The prevalence of leprosy is not evenly distributed, as much of the disease seen today occurs in the third world. Most cases (72%) are from Asia and Oceania, whereas 18% are from Africa and only 7% are from the Americas (Lockwood and McAdam, 1998).

The genome of the 1–8 µm long and 0.3–0.5 µm wide *M. leprae* bacillus is approximately 3.2 MB (Gelber and Rea, 2000). The sequence

has been partially determined and is available for inspection (<http://www.sanger.ac.uk/DataSearch>). It is speculated that many of the genes essential for the survival of *M. leprae* in the environment have been deleted, and the bacillus has become an obligate parasite of its human host. Indeed to date no one has been able to continuously culture the bacillus in either in vitro conditions or cell culture. It may be true that the mycobacterium has lost genes essential for survival in these ex vivo conditions and thus has an absolute requirement for host factors (Gelber and Rea, 2000). In fact, the only methods to propagate *M. leprae* bacilli are via animal infections with either 9-banded armadillos or severe combined immunodeficiency (SCID) mice. Growth of sufficient bacilli for laboratory manipulation takes approximately one year, inasmuch as the generation time for this organism is approximately 14 days in animal tissues.

Leprosy is a chronic disease with a long incubation period. This fact is affirmed by the observation that children younger than two years do not have leprosy symptoms. In addition, people residing in nonendemic countries who have visited a site with endemic leprosy may develop the disease many years after the initial exposure. Hence the incubation period is estimated to range from 2–12 years. Like those infected with TB, only about 10% of those infected with leprosy go on to develop the disease (Lockwood and McAdam, 1998). Being a human disease, leprosy has no established natural reservoir for infection. *Mycobacterium leprae* is probably transmitted from person to person although the reservoirs and their role in transmission remain controversial issues. In 1898 Schaffer noted that leprosy patients discharged large numbers of acid-fast bacilli (AFB) when coughing, sneezing or speaking normally. In fact, if left untreated a lepromatous leprosy patient may dispel 6.8×10^{10} AFB in a single nose blow. Thus leprosy may be transmitted via an aerosol route where it goes on to infect the lining of the nose (Lockwood and McAdam, 1998). Though *M. leprae* produces lesions that often involve the extremities and skin, bacilli probably reach these locations by hematogenous spread. In fact people who have leprosy may have granulomata in the lymph nodes, liver, kidney, spleen, bone marrow, adrenals, testes and eyes. Thus the bacilli can spread to remote portions of the body to cause lesions. Although *M. leprae* spreads through the body via a systemic route, it prefers to grow at temperatures below 37°C and therefore has a tropism for the extremities and skin where its growth can flourish.

The outcome of the disease is strongly dependent on the host's immune response. Upon infection, bacilli are engulfed by macrophages. If the

macrophages are sufficiently activated to kill the invading bacilli, then the infection will be cleared. Otherwise, the bacilli will go on to replicate within macrophages, lyse the cells, and infect other macrophages (Gelber and Rea, 2000). The host's immune system can take one of two pathways. First, the disease is controlled by strong cell-mediated immunity employing helper T cells of the Th1 lineage. These helper T-cells induce the macrophages to kill the bacilli, and INF- γ and IL-2 are found at the site of infection (Lockwood and McAdam, 1998). Organized granulomata are composed of the macrophages surrounded by the T-cells, resulting in what is known as tuberculoid or paucibacillary leprosy. It is known from the days before antibiotic therapy that tuberculoid leprosy often spontaneously heals (Lockwood and McAdam, 1998). However, tuberculoid leprosy also may result in tissue damage from continuous lymphocyte infiltration into the area of infection. Tuberculoid leprosy has a shorter incubation time, generally 2–5 years, and causes few skin lesions. (Lesions when manifest are hypopigmented and asymmetric.) Nerve damage can occur when granulomata are near small dermal sensory and autonomic nerve fibers (Lockwood and McAdam, 1998). Tuberculoid leprosy is not associated with the presence of stainable *M. leprae* in skin and does not produce upper respiratory signs and symptoms. The reason is probably that strong cell-mediated immunity controls the infection, though the control is at the expense of significant tissue damage. In general, tuberculoid leprosy has a good prognosis with treatment.

The other path of infection occurs in patients who do not have good cell-mediated immunity and good initial killing of the *M. leprae*. In this expression of the disease, named “lepromatous” or “multibacillary” leprosy, bacilli multiply out of control. This form of the disease has a somewhat longer incubation period, 8–12 years. The bacilli may invade Schwann cells, resulting in demyelination of nerves and nerve damage (Lockwood and McAdam, 1998). Granulomata that do form are poorly organized, with high bacterial loads. Bacilli may replicate within dermal cells as evidenced by AFB in the skin. Most (80% of) lepromatous patients have some nasal symptoms due to invasion of the nasal mucosa by *M. leprae*. Occasionally, without treatment, the bacilli may cause so much destruction that the nasal septum collapses. In addition, denervation and loss of pain sensation results in repetitive trauma and injury to limbs. Destruction can occur over vast areas of limbs that in some instances may necessitate amputation.

In between the two extremes or poles, tuberculoid and lepromatous, there is a continuum. These disease states, which are defined patholog-

ically after review of skin biopsy specimens, are referred to as borderline tuberculoid, borderline leprosy and borderline lepromatous. Borderline tuberculoid has some aspects of lepromatous leprosy, whereas borderline lepromatous leprosy has some aspects of tuberculoid leprosy. Borderline leprosy refers to a state in between lepromatous and tuberculoid. Borderline states are extremely unstable and may shift spontaneously between mild and severe disease.

Until recently not much was known about the mechanism by which *M. leprae* interacts with and causes damage to cells of the nervous system. Recent evidence has revealed that *M. leprae* binds to the basal lamina surrounding Schwann cells through an interaction between a 21-kDa surface protein on *M. leprae* and laminin-2 within the basal lamina (Rambukkana et al., 1997; Shimoji et al., 1999). Additionally, *M. leprae* can interact directly with Schwann cells by binding to α -dystroglycan on the Schwann cell surface. This interaction, however, occurs only in the presence of laminin-2 (Rambukkana et al., 1998). These findings have the promise of providing mechanistic information that may aid in the development of improved therapeutics against leprosy.

MYCOBACTERIUM KANSASII This slow-growing organism is the second most frequent cause of pulmonary disease by a nontuberculous mycobacteria (Brown and Wallace, 2004). *Mycobacterium kansasii* is found in environmental water, and water is probably the source of human infection (Iseman, 1998). The clinical presentations of pulmonary *M. kansasii* are a chronic cough, low-grade fever, malaise and chest pain. Though clinical manifestations are similar to those caused by *M. tuberculosis*, a chest x-ray usually reveals upper-zone disease with fewer fibronodular regions than found with either *M. tuberculosis* or MAC. Predisposing factors for infection with *M. kansasii* are smoking-induced chronic bronchitis, chronic inorganic dust exposure, and chronic obstructive pulmonary disease (Toosi and Ellner, 1998). Although extrapulmonary infections are rare, *M. kansasii* can cause diffuse cutaneous disease as well as cervical lymphadenitis, especially in children. Patients with AIDS or with impaired cellular immunity may also develop a disseminated infection.

MYCOBACTERIUM MARINUM *M. marinum* causes a cutaneous disease in humans known as swimming pool granuloma, fish handler's nodule or surfer's nodule. As implied above, water is the major environmental reservoir for this mycobacterial species (Toosi and Ellner, 1998). The bacterium and therefore most cases of infection are mainly found in the coastal areas of North America (Ise-

man, 1998). Humans contract the disease from environmental water, the handling of domestic and wild fish, or the cleaning and maintenance of fish tanks. *Mycobacterium marinum* lesions appear on the extremities of affected individuals, as the bacillus is most adept at growing at a temperature of 32°C (Brown and Wallace, 2004). Interestingly, *M. marinum* is closely related to *M. tuberculosis* on a genetic level. Because *M. marinum* is not transmitted to humans through an aerosol route and is not considered a biosafety level 3 (BSL3) organism, it has been used as a model system for the study of *M. tuberculosis* pathogenesis (Ramakrishnan et al., 2000). In animal tissues, *M. marinum* bacilli infect macrophages and this leads to granuloma formation. As this species of mycobacterium causes disease in both fish and frogs, the nature of its pathogenesis has been investigated in these animal models. Thus, although *M. marinum* is not a major public health problem, research into its basic biology is ongoing due to its genetic similarity with *M. tuberculosis*.

MYCOBACTERIUM SCROFULACEUM This slowly growing mycobacterium, first isolated in 1956, has an optimal growth temperature of 37°C and, upon initial isolation, can take approximately 4 to 6 weeks to achieve growth. It is a leading cause of scrofula or cervical lymphadenitis in children 1 to 5 years of age. Infrequently it may cause progressive pulmonary disease as well as bone and soft tissue disease and, in some instances, disseminated disease.

MYCOBACTERIUM FORTUITUM, M. CHELONAE and M. ABSCESSUS These organisms comprise a group of rapidly growing mycobacteria that are found in soil samples as well as in water; however, their mode of transmission to humans remains unknown (Iseman, 1998). These mycobacteria cause localized infection of the skin, soft tissues and bones. They also may cause pulmonary disease typified by a persistent hacking cough, low-grade fever, chills, malaise and mucopurulent secretions.

MYCOBACTERIUM ULCERANS During the first half of the 20th century this mycobacterial disease was recognized in Bairnsdale, Australia. The syndrome produced an ulcer, subsequently named the "Bairnsdale ulcer," or "Buruli ulcer," that was characterized by a chronic progressive ulceration of the skin (Fig. 10). Acid-fast bacilli, later identified as *M. ulcerans*, were eventually cultivated from lesions of infected individuals. Although no bacteria have been cultivated from environmental sources, the use of polymerase chain reaction (PCR) has identified *M. ulcerans* in water sources (Ross et al., 1997). Thus it is

Fig. 10. A young boy infected with *M. ulcerans* has a buruli ulcer covering a portion of his torso. From Connor et al. (1976).

hypothesized that *M. ulcerans* is acquired from the environment via water. Indeed it has been noted that people inhabiting areas close to a body of stagnant water in tropical regions are more at risk for developing a Buruli ulcer (Ross et al., 1997; Johnson et al., 1999). The hallmark of the disease is a skin ulcer that begins as a small nodule but (if left untreated) enlarges to encompass a large surface area. The ulcers are themselves painless, suggesting that there is some nerve involvement. Inflammatory response at the site of colonization by the AFB or the site of ulceration appears to be minimal, even though necrosis of the subcutaneous fat tissue is extensive. In contrast to *M. tuberculosis*, *M. ulcerans* grows as microcolonies extracellularly during human infection. In addition, treatment of the disease is not trivial. Antibiotic therapy has variable efficacy, and therefore the best treatment is surgical excision after the ulcer has been identified at an early nodule stage. Large ulcers require extensive surgery with skin grafting. In extreme cases where muscle tissue is involved, amputation of an affected limb may be required (Iseman, 1998).

It has long been suspected that a toxin mediates the extensive tissue damage associated with

the Buruli ulcer (Johnson et al., 1999). The fact that tissue necrosis occurs at sites distal to areas of colonization by *M. ulcerans* seems to imply that a factor that can diffuse to distant tissues is involved. It has recently been discovered that a polyketide toxin named “mycolactone” is responsible for histopathologic changes distal to the site of infection (George et al., 1998; George et al., 1999). This toxin was present in the culture filtrates of growing *M. ulcerans*, indicating that it is secreted into the milieu of the bacterium. When this toxin is injected into guinea pig skin, ulcers similar to those caused by *M. ulcerans* are formed. In addition, exposure of L929 murine fibroblasts to the toxin arrests their cell cycle. Thus, as a toxinogenic microorganism, *M. ulcerans* has a mode of pathogenesis that is very different from that of other members of the genus *Mycobacterium*.

PREVENTION Vaccination with the attenuated *M. bovis* strain bacille Calmette Guérin (BCG) is common in many parts of the world; however, protection rates due to this vaccine vary from 0–80%. Whereas BCG probably provides little protection against adult pulmonary TB, it does appear to protect against childhood disseminated TB (Colditz et al., 1994). An additional problem of vaccination is that (once vaccinated with BCG) individuals will have a positive reaction to the administration of purified protein derivative (PPD) from *M. tuberculosis*, excluding its use as a diagnostic tool. Therefore once a person has been vaccinated, it is impossible to know if they have been infected with *M. tuberculosis* subsequently and therefore if their risk of developing active disease is substantial. Thus in the United States vaccination is not recommended as a measure to control *M. tuberculosis* spread. In the United States and many European nations, it is preferable to periodically administer PPD to persons at high risk of becoming infected with *M. tuberculosis* and to treat prophylactically with antibiotics. Vaccination, however, is useful in reducing miliary and meningeal disease in children in third world countries where tuberculosis rates are high and mass screening is impractical.

Mycobacterium leprae

THOMAS M. SHINNICK

Although *Mycobacterium leprae* was one of the first bacterial pathogens of humans to be described (Hansen, 1874), progress on understanding the basic biology and pathogenicity of this organism has been greatly hampered by the inability to find a conventional laboratory medium or tissue culture system that can support its growth. Consequently, the only means of propagating this organism at present is by using experimental animals. Furthermore, it has been found that the nine-banded armadillo can be used to produce large numbers of bacilli (Kirchheimer and Storrs, 1971; Storrs, 1971). Relatively little is known, therefore, about the taxonomy, genetics, and biochemistry of this species. A corollary of this is that much of what we do know about *M. leprae* has come from studies of the disease it causes (leprosy or Hansen's disease) and from the animal models. As such, this chapter emphasizes the characteristics and behavior of *M. leprae* in experimental animal model systems and in humans. Several excellent reviews on the clinical aspects, epidemiology, immunology, and pathology of leprosy and on the biochemistry and immunochemistry of *M. leprae* have been published recently, and the reader is referred to these for additional information (Bloom and Godal, 1983; Bloom and Mehra, 1984; Fine, 1982; Gaylord and Brennan, 1987; Hastings, 1986; Hastings and Franzblau, 1988; Jopling and McDougall, 1988; Kaplan and Cohn, 1986; Stewart-Tull, 1982).

Although *M. leprae* can occasionally be found in the body extracellularly, the bacillus appears to be able to replicate only within cells of the host, most commonly in macrophages and Schwann cells (Bloom and Godal, 1983; Kaplan and Cohn, 1986). Hence, *M. leprae* is considered to be an obligate intracellular pathogen. In host cells, the bacilli are found singly or in clumps referred to as *globi* (Cowdry, 1940). The bacilli are straight or slightly curved, Gram-positive, acid-fast, alcohol-fast, nonmotile rods ranging from 1 to 8 μm in length and 0.2 to 0.5 μm in width (Draper, 1983). Acid- and alcohol-fastness refers to the ability of the bacillus to retain the color of certain dyes, usually carbol fuchsin, following treatment with mild acid and alcohol, respectively.

M. leprae has been placed in the genus *Mycobacterium* in the family Actinomycetales based mainly on cell structure, staining properties and chemical composition as well as on the basis of the presence of mycolic acids, antigens characteristic of mycobacteria, and a lipid-rich cell envelope (Draper, 1976; Harboe et al., 1977; Stanford et al., 1975). For example, the *M. leprae* bacillus closely resembles *M. tuberculosis* bacilli in size, morphology, and staining characteristics, although it does stain a little more deeply with carbol fuchsin and the staining is somewhat less acid fast. Recently, analyses of the ribosomal RNA sequences of armadillo-grown *M. leprae* by nucleic acid hybridization techniques (Sela et al., 1989) and by ribosomal RNA sequence compar-

isons (Smida et al., 1988) revealed that *M. leprae* is closely related to the corynebacteria, nocardia, and mycobacteria, especially to the two slowly growing *Mycobacterium* species *M. avium* and *M. tuberculosis*. Although these observations indicate that *M. leprae* should be classified in the genus *Mycobacterium*, several features distinguish *M. leprae* from other members of the *Mycobacterium* genus. These are: 1) loss of acid-fastness upon extraction with pyridine, although *M. smegmatis*, *M. vaccae*, and *M. phlei* do lose acid fastness after prolonged exposure to pyridine (Fisher and Barksdale, 1971; McCormick and Sanchez, 1979; Skinsnes et al., 1975); 2) ability to oxidize 3,4-dihydroxyphenylalanine (Prabhakaran and Kirchheimer, 1966); 3) replacement of L-alanine with glycine in the linking peptide of peptidoglycan (Draper, 1976); 4) 56% GC content as compared with 65–70% for most *Mycobacterium* species (Clark-Curtiss et al., 1985; Imaeda et al., 1982; Wayne and Gross, 1968); and 5) lack of substantial genomic DNA homology with other *Mycobacterium* species (quite in contrast with the ribosomal rRNA results) (Athwal et al., 1984; Grosskinski et al., 1989). Although these differences are not sufficient to exclude *M. leprae* from the genus *Mycobacterium*, they are sufficient to render the final taxonomic position of *M. leprae* somewhat in doubt.

The Disease

Hansen's disease (leprosy) is a chronic infectious granulomatous disease that primarily affects the peripheral nervous system, skin, and mucous membranes, especially nasal mucosa. In advanced cases, other tissues—including muscle, testes, capillary endothelium, liver, spleen, and bone marrow—can be affected (Desikan and Job, 1968). Although leprosy is not usually fatal in and of itself, 20–30% of patients with untreated or neglected infections develop crippling deformities of hands and feet. A sequela of these deformities is the social stigma that has been historically associated with leprosy. An addition consequence is that suicide is a common cause of death among infected individuals, particularly during episodes of exacerbation of the lesions (erythema nodosum leprosum).

Leprosy has been estimated to afflict 10–12 million individuals world-wide, with most cases being found in tropical and subtropical regions (Sixth Report of the WHO Expert Committee

on Leprosy, 1988). Climatic factors do not seem to have a significant impact on the disease, however, since leprosy was widespread in Europe, particularly Norway, in the past centuries (Browne, 1975), and cases have been reported from above the Arctic Circle (Sansarricq, 1981). Within endemic areas, cases of leprosy appear to cluster geographically, with the prevalence of disease exceeding 10 cases per 1000 population in the high prevalence areas (Bloom and Godal, 1983). Although this disease has been cited as the "least infectious" of communicable diseases (McWhirter, 1981), epidemics of leprosy have occurred on some Pacific Islands in which as much as 35% of the population developed the disease over a 20-year period (Wade and Ledowski, 1952).

A feature of the disease that has intrigued clinicians and immunologists is the variety of clinical manifestations that can be found. These range from a single lesion with no detectable bacilli to multiple lesions containing large numbers of bacilli. Bacterial counts up to 5×10^9 organisms per gram of tissue have been found (Collaborative effort, 1975). The variety of disease symptoms is not related to the genetics of the bacterium but rather to the immune responsiveness of the host (Bloom and Mehra, 1984; Kaplan and Cohn, 1986). A clinically and experimentally useful categorization of this disease spectrum is the Ridley-Jopling classification scheme which is based on immunopathologic features of the disease (Ridley and Jopling, 1966). Tuberculoid leprosy (TT) is at one pole of the spectrum and is characterized by one or a few localized skin or nerve lesions, a strong cellular immune response, and a weak humoral immune response. Histologically, one finds well-organized epithelioid cell granulomas with multinucleated giant cells and abundant lymphocytes in TT lesions, but bacilli are usually absent ($<10^5$ bacilli/gram of tissue). At the other extreme is lepromatous leprosy (LL), characterized by numerous small, bilaterally symmetrical skin lesions, a weak or absent cellular immune response, and high antibody titers. Histologically, one observes a foamy macrophage granuloma with few lymphocytes in LL lesions, and the macrophages contain numerous bacilli ($>10^8$ bacilli/gram). Within these extremes are other conditions, including borderline lepromatous (BL; numerous skin lesions, numerous bacilli, granulomas with undifferentiated macrophages and histiocytes), borderline (BB; numerous skin lesions, few acid-fast bacilli, nerve involvement, epithelioid cell granulomas with no giant cells), and borderline tuberculoid (BT; multiple skin lesions, occasional bacilli, nerve involvement, diffuse epithelioid cell granulomas). One additional category, called indeterminant leprosy,

often found when a patient first seeks treatment, usually consists of a single small hypopigmented plaque. Such a lesion may remain indeterminant, regress spontaneously, or progress into a lesion that falls into one of the above categories.

It is generally accepted that *Mycobacterium leprae* is the etiologic agent of leprosy. However, not all of Koch's postulates have been fulfilled for identifying *M. leprae* as the causative agent of human leprosy. That is, a pure culture of *M. leprae* has not been developed from a single bacillus and shown to cause disease. The inability to grow the organism outside of animal hosts is the major stumbling block to completing Koch's postulates. Nonetheless, much evidence has accumulated in support of the role of *M. leprae* as the agent of the disease. The evidence includes the following: 1) *M. leprae* is found in leprosy patients and not in nonleprosy patients; 2) *M. leprae* bacilli are invariably present in lepromatous lesions; 3) leprosy patients display characteristic immune responses to *M. leprae* antigens (Mitsuda and Fernandez reactions; see Jopling and McDougall, 1988); 4) antibodies and T-cells reactive with antigens or epitopes uniquely expressed by *M. leprae* can be isolated from leprosy patients (reviewed in Gaylord and Brennan, 1987); 5) a phenolic glycolipid (PGL-I; Hunter and Brennan, 1981; Hunter et al., 1982) uniquely found in *M. leprae* is also uniquely found in lesions, sera, and urines from leprosy patients (Cho et al., 1983; Cho et al., 1986; Koster et al., 1987; Vemuri et al., 1985; Young et al., 1985); 6) *M. leprae*-specific nucleotide sequences can be found in leprosy lesions (Clark-Curtiss and Docherty, 1989); and 7) drug susceptibility of *M. leprae* in animal models parallels drug efficacy in patients (reviewed in Shepard, 1986).

Several properties of the *M. leprae* bacillus contribute to the features of the disease:

1. *M. leprae* has a generation time of 11–13 days in experimental animals (Levy, 1976; Shepard and McRae, 1971b). Such slow growth might influence the length of time from infection to disease (median interval 2–8 years; Fine, 1982) and the chronic nature of the infection.
2. *M. leprae* grows best at 30°C, which may explain its affinity for cooler parts of the body including skin and nasal mucosa (Shepard, 1965).
3. *M. leprae* infects Schwann cells and is the only bacterial pathogen capable of entering peripheral nerves (Job, 1971; Ridley et al., 1987; Stoner, 1979). These facets play a role in the loss of nerve function and the generation of crippling deformities.
4. *M. leprae* can suppress the cellular immune response, perhaps through induction of suppressor T-cells (Bloom and Mehra, 1984;

Mehra et al., 1984) and/or rendering the infected macrophage defective for activation or antigen processing (Desai et al., 1989; Prasad et al., 1987; Sibley and Krahenbuhl, 1988). This may allow the host to tolerate the large bacterial load seen in lepromatous leprosy patients (up to 10^{13} organisms).

5. The unique phenolic glycolipid of *M. leprae*, called PGL-I, is a major component of the cell envelope (2% of total bacterial mass; Hunter and Brennan, 1981), can scavenge hydroxyl radicals and superoxide anions in vitro (Chan et al., 1989) and can inhibit the oxidative response in macrophages that have ingested *M. leprae* (Vachula et al., 1989). Hence, PGL-I may play a role in the ability of the bacteria to survive within macrophages and may also play a role in immunosuppression (Mehra et al., 1984; Prasad et al., 1987).

6. *M. leprae* can survive and multiply within macrophages and Schwann cells. Three possible strategies of intracellular survival have been proposed for *M. leprae*. First, *M. leprae* bacilli might avoid the bactericidal activities of the phagocytic cells by escaping from the phagosome (phagolysosome?) and multiplying in the cytoplasm of the infected cells (Mor, 1983). Second, viable *M. leprae* has been reported to prevent the fusion of phagosomes and lysosomes in murine macrophages (Frehel and Rastogi, 1987; Sibley et al., 1987), but not in Schwann cells (Steinhoff et al., 1989). A similar prevention of phagosome-lysosome fusion is an intracellular survival strategy used by *M. tuberculosis* (d'Arcy Hart, 1982). Third, inside phagosomes *M. leprae* generates around the bacillus a characteristic electron microscope image called an "electron transparent zone (ETZ)" (Draper and Rees, 1970). The ETZ might represent a physical barrier to prevent degradative or bactericidal proteins of the lysosome from reaching the bacterial surface. Regardless of the precise strategy used, one result of evading the bactericidal and degradative activities of the phagocytic cells might be that the *M. leprae* antigens would be less likely to be processed and presented to the immune system. If so, the bacilli might thereby prevent or escape a protective immune response.

Habitat

Leprosy and *M. leprae* have historically been considered to be confined to humans. Indeed, humans are the major host and reservoir of the leprosy bacillus. Humans, however, are not the only possible habitat for *M. leprae*. Naturally acquired, leprosy-like infections have been

observed in armadillos (*Dasypus novemcinctus*; Walsh et al., 1975), chimpanzees (*Pan troglodytes*; Donham and Leininger, 1977), and Mangabey monkeys (*Cercocebus torquatus atys*; Meyers et al., 1985). Since the bacilli infecting these animal species are identical to the human pathogen, based on a variety of DNA homology and biochemical studies (Athwal et al., 1984; Clark-Curtiss and Walsh, 1989; Meyers et al., 1985), leprosy should be considered a zoonotic disease (Walsh et al., 1981). Furthermore, the possibility of the transmission of *M. leprae* from animals to humans has been raised by the observation that five armadillo handlers in Texas developed leprosy in the absence of any known contact with a human source of *M. leprae* (Lumpkin et al., 1983).

The isolation of *M. leprae* from soil in Bombay and other environmental sources has also been reported (Kazda, 1981a; Kazda et al., 1986). It is unclear, however, if these reports identify an environmental niche for *M. leprae* or if the isolated bacilli represent "environmental contamination" from *M. leprae*-infected individuals. For example, one possible source of "environmental contamination" might be nasal secretions of lepromatous leprosy patients (see below). Finally, free-living amoebae have been suggested as a potential reservoir for *M. leprae* (Grange and Rowbotham, 1987), although no convincing evidence for the presence or multiplication of *M. leprae* in amoebae has been published.

The mode of transmission of the leprosy bacillus remains unknown. Evidence is accumulating that infection occurs predominantly by way of the respiratory route, although other routes may be responsible for some cases (reviewed in Pallen and McDermott, 1986). Some of the evidence for respiratory transmission includes: 1) the epidemiology of transmission is consistent with spread by a respiratory route (Barton, 1974; Davey and Rees, 1974). 2) The major portal of exit of the leprosy bacillus is the nose. Lepromatous leprosy patients can shed up to 10^8 bacilli per day in nasal discharges, and the bacilli can survive for several days in dried secretions (Davey and Rees, 1974; Shepard, 1962). 3) Bacilli can be aerosolized by coughing and sneezing. 4) The nose has been suggested as a possible site of initial infection in humans (Pallen and McDermott, 1986), and immunodeficient mice can be infected by exposing them to an aerosol containing *M. leprae* (Rees and McDougall, 1976; Chehl et al., 1985). 5) As originally discussed by Koch (1897) and Schaffer (1898), the similarities between tuberculosis and leprosy (e.g., the similarity between the large numbers of *M. leprae* in nasal secretions and the large numbers of *M. tuberculosis* in sputa) are suggestive of an analogous route of transmission.

At present, however, one can not exclude transmission by skin-to-skin contact or by insect vectors. For example, ulcerating skin lesions could be a source of bacilli that might enter a susceptible host through a skin abrasion. Similarly, broken skin might be a portal of entry for bacilli that were aerosolized or otherwise deposited in the environment. With respect to insect vectors, *M. leprae* can be found in flies that have fed on nasal secretions from lepromatous leprosy patients (Greater, 1975; Kirchheimer, 1976), and the transmission of *M. leprae* from humans to mouse footpad by a mosquito vector (*Aedes aegypti*) has been reported (Narayanan et al., 1977). Another possible route is via breast milk since *M. leprae* bacilli can be found in the breast milk of lepromatous patients (Pedley, 1968). The role, if any, of the gastrointestinal tract in the transmission of leprosy is not known. Finally, occasional cases of leprosy may result from accidental inoculation of susceptible individuals by needle prick (Wade, 1948).

Isolation and Propagation

The currently available methods for the isolation and propagation of *M. leprae* are greatly constrained by the lack of an axenic or cell-culture cultivation system. In the laboratory, *M. leprae* has been propagated in both immunocompetent and immunodeficient mice and rats (Colston and Hilson, 1976; Fieldsteel and Levy, 1976; Hilson, 1965; Rees, 1966; Shepard, 1960), hamsters (Binford, 1959), armadillos (Kirchheimer and Storrs, 1971), and in Mangabey, Rhesus, and African green monkeys (Wolf et al., 1985). The features of the growth and pathology of *M. leprae* in each species are somewhat different, and the choice of animal model often depends on exactly what experimental question is being asked (reviewed in Shepard, 1986).

Staining Methods

One consequence of having only animal systems in which to propagate *M. leprae* is that much of the work depends on the enumeration of acid-fast bacilli by direct counting in microscopic fields. The standard staining method is a modified Ziehl-Neelsen technique (e.g., see Jenkins et al., 1982, or Jopling and McDougall, 1988). Briefly, bacilli on a glass slide are covered with a carbol-fuchsin solution and left at room temperature for 20 minutes (cold Ziehl-Neelsen) or heated for 15 minutes over a boiling water bath (hot Ziehl-Neelsen). The slide is washed with water, destained with 1% hydrochloric acid in 70% ethanol, and washed again with water. The sample is then counterstained with 1% methyl-

ene blue, washed in water, and air dried. Several methods for the actual counting of bacilli in the microscope and for using the counts to determine the concentration of bacilli in a sample have been described (Hanks et al., 1964; Shepard and McRae, 1968). The uniformity of staining exhibited by a bacillus is used as an indication of the viability of the bacillus (Hansen and Looft, 1895; Shepard and McRae, 1965a; Waters and Rees, 1962). Rods showing uniform staining are considered to be viable, while bacilli displaying fragmented or granular staining are considered non viable. A "morphologic index" is calculated as the percentage of uniformly staining bacilli and has been used to follow the progress of chemotherapy (Waters and Rees, 1962).

Propagation in Mice

The most frequently used propagation system is growth in the footpad of immunocompetent mice, as was originally described in the landmark paper of Shepard (1960). In this animal model, one typically propagates *M. leprae* by injecting mice subcutaneously with about 5×10^3 bacilli in one of the hind footpads, although as few as 1–10 bacilli are sufficient to establish an infection (Shepard and McRae, 1965a). A typical growth curve displays an initial lag phase followed by logarithmic growth with a doubling time of 11–13 days and a stationary phase with a plateau level of about $1\text{--}2 \times 10^6$ bacilli per footpad. The plateau level is thought to be due to development of a cell-mediated immune response to the bacillus. As a consequence, the viability of the *M. leprae* in the footpad decreases dramatically during the plateau phase. Thus, to propagate a strain one should harvest bacilli prior to or early in the plateau phase.

A typical growth curve is accompanied by a typical histopathologic picture. Early in infection one finds single bacilli or small clumps of 2–5 bacilli aligned in a parallel fashion ("cigar packs") in tissue macrophages, muscle, and tendon cells. Later, a cellular infiltrate mainly of macrophages and a few lymphocytes appears, followed by development of a microscopic granuloma with a few large, "foamy" macrophages in the center surrounded by a loose collection of macrophages and lymphocytes. The large macrophages contain numerous bacilli. In late stages, one occasionally observes invasion of the nerves.

In the absence of a T-cell response, multiplication continues to much higher levels. Thus, immunodeficient animals such as thymectomized-irradiated mice (Rees, 1966), neonatally thymectomized Lewis rats (Fieldsteel and Levy, 1976), and nude mice (*nu/nu*) (Colston and Hilson, 1976; Chehl et al., 1983) have been used to propagate *M. leprae*. The minimum infec-

tious dose and generation time during logarithmic growth appear to be the same in the immunodeficient animals as in immunocompetent animals. The bacilli, however, can multiply to up to about 10^9 cells per foot pad in the neonatally thymectomized Lewis rat and about 5×10^{10} cells per footpad in the nude mouse. In the nude mouse one frequently observes spread of the *M. leprae* to other cool sites in the body (e.g., the ears) and invasion into nerves. Overall, the histopathology of the disease in the immunodeficient mice resembles that of human lepromatous leprosy. One drawback to the use of these animals on a routine basis is that they are particularly susceptible to a variety of other infections, and hence, special precautions need to be taken to ensure the survival of the animals for the duration of the experiment (often greater than 1 year).

Propagation in the Armadillo

A second major advance in leprosy research was the development of the nine-banded armadillo as an animal model system for the propagation of *M. leprae* (Kirchheimer and Storrs, 1971; Storrs, 1971). The key here is that in the armadillo the disease resembles human lepromatous leprosy and one can isolate very large numbers of bacilli from each infected armadillo. For example, the bacillary load in lesions can reach 10^{10} organisms per gram of tissue, and the total bacillary load can exceed 10^{12} bacilli per armadillo. Also, the liver and spleen are heavily infected and are easily manipulated sources of bacilli. The availability of the large amounts of *M. leprae* from armadillos opened the way for biochemical and molecular biologic analyses of the bacillus as well as provided a way to produce sufficient *M. leprae* for use in vaccine trials. One technical problem with the use of armadillos is that the *M. leprae* infection is fatal for the armadillo. Hence, to maximize bacillary yield and avoid postmortem contamination of tissues with other bacteria, care must be taken to sacrifice the animal and harvest bacilli just prior to the animal succumbing to the *M. leprae* infection itself. Finally, one must be aware that armadillos may harbor other naturally acquired, fastidious, acid-fast mycobacteria (Kazda, 1981b) and may harbor naturally acquired *M. leprae* (Walsh et al., 1975).

Primate Infection

Naturally occurring *M. leprae* infections have been observed in several primates, and *M. leprae* has been experimentally transmitted to three species of monkeys (Wolf et al., 1985). While the disease in these animals seems to parallel closely disease in humans, their use in the routine isola-

tion and propagation of *M. leprae* is deterred by economic and humane concerns. Nonetheless, the primates may prove to be important model systems for studies on pathology, immunology, and vaccine development.

Maintenance of Viable Cells

Finally, a concern of those working with *M. leprae* is that the bacillus does not store well. Good viability of *M. leprae* in suspensions or in biopsy specimens is maintained for 7–10 days at 0–4°C (Shepard and McRae, 1965b). For long-term storage, one can store the bacilli in liquid nitrogen. Three important points here are: 1) the sample should contain 10% dimethyl sulfoxide or 10% glycerol; 2) slow freezing is required (<1°C/min); and 3) the bacilli rapidly lose viability upon repeated freezing and thawing (Colston and Hilson, 1979; Portaels et al., 1988). For routine laboratory work one usually maintains several stocks of *M. leprae* in continuous serial passage. Of course, one is concerned that serial passaging of *M. leprae*, which typically involves transfer of 10^3 to 10^4 bacilli from mouse to mouse, might lead to changes in the bacillus, e.g., outgrowth of variants. However, some strains have been serially passaged in the Hansen's Disease Laboratory at the Centers for Disease Control (CDC) for over 25 years without any detectable changes in growth pattern (rate and plateau level) or histopathology of infection. Furthermore, by restriction-fragment-length-polymorphism (RFLP) studies, Clark-Curtiss and Walsh (1989) have found that the *M. leprae* bacilli isolated from leprosy patients in India, armadillos in Louisiana, and a naturally infected Mangabey monkey were virtually identical. This exceptional conservation of nucleotide sequence might be related to the long generation time of *M. leprae* or to the presence of a very efficient DNA-damage-repair system. Overall, these observations suggest that *M. leprae* changes very slowly, if at all, during serial passaging.

Isolation from Clinical Specimens

With respect to the isolation of *M. leprae* from a clinical specimen (e.g., biopsy of an LL lesion), the first steps are usually to purify the bacilli and to inject them into the footpad of an immunocompetent mouse such as the BALB/c or CFW strain (reviewed in Shepard, 1986). To purify the bacilli, the usual procedure is to release the bacilli from their intracellular location within a biopsy of infected tissue by mincing the sample, suspending it in Hank's Balanced Salt solution containing 0.1% BSA, and homogenizing it in the presence of 2 to 3-mm-diameter glass beads. To reduce potential contamination with other

bacteria, the sample can be treated with 0.5M NaOH for 15 minutes and then neutralized with HCl. Following this treatment, the cells are usually harvested by centrifugation and resuspended in Hank's Balanced Salt solution containing 0.1% BSA. Samples of the bacterial suspension are stained and examined microscopically to determine the number of uniformly staining, acid-fast bacilli. One then injects portions of the samples containing 10^4 or fewer bacilli into the footpads of mice. Tissues from the mice are harvested periodically and examined for the presence and numbers of acid-fast bacilli and the histopathology of the site of infection.

These initial steps allow one to produce sufficient bacilli to begin the process of determining if the isolated organism is *M. leprae* (described below). In addition, the rate of growth in the footpad and the histopathology of the infection in the mouse footpad may be useful in distinguishing *M. leprae* from other mycobacteria (Shepard, 1986). That is, only *M. leprae*, *M. lepraemurium*, *M. marinum*, and *M. ulcerans* of the *Mycobacterium* species grow in the mouse footpad, and each displays a characteristic growth rate and histopathology. For example, *M. marinum* infections appear in about 2 weeks and often cause ulceration at the site of inoculation.

Identification

The lack of an in vitro system for the cultivation of *M. leprae* makes positive identification particularly difficult. Often a presumptive identification of an organism as *M. leprae* is made based simply on two observations—staining characteristics and lack of growth on conventional laboratory media. For example, with clinical specimens, any noncultivable, acid-fast, rod-shaped bacillus isolated from a site displaying a histopathology characteristic of a leprosy lesion is presumed to be *M. leprae*. Although such a definition is adequate for decisions on patient management, it is not particularly useful if one is trying to identify an organism isolated from a source devoid of histopathologic information, such as nasal secretions or the environment. Also, such a definition is clearly insufficient to prove an organism is *M. leprae*. Undoubtedly, the imprecise nature of the definition has contributed to the numerous erroneous claims for the cultivation of *M. leprae* in vitro.

Until recently, only a few rather labor-intensive, time-consuming, and technically difficult tests, such as growth in mouse footpads or presence of *M. leprae*-specific components, were available to confirm the presumptive identification. Fortunately, a variety of relatively simple biochemical, immunological, and molecular-

biological tests is now becoming available that should allow a rapid and definitive identification of *M. leprae*. Some of the potentially useful identification tests are: 1) morphology and staining characteristics; 2) failure to grow on bacteriologic media; 3) growth and histopathology in animal models; 4) drug susceptibility patterns; 5) presence of unique biochemical components or activities; 6) presence of characteristic antigens; and 7) presence of specific nucleotide sequences.

The identification process still starts with an examination of the staining characteristics of the bacilli. *M. leprae* bacilli isolated from lesions are Gram-positive rods. The carbol fuchsin stain is not extractable with acid or alcohol but is extractable with pyridine (Fisher and Barksdale, 1971). Of the other mycobacteria, only *M. smegmatis*, *M. vaccae*, and *M. phlei* display somewhat similar pyridine-extractable acid-fast characteristics (McCormick and Sanchez, 1979; Skinsnes et al., 1975). An important caveat here is that absence of acid-fastness can not be taken as an indication that the organism is not *M. leprae*, since a variety of mycobacteria lose the acid-fast characteristic at various times during their growth.

The second routinely used test is a determination of growth on any of a variety of media used for the propagation of mycobacteria, such as Lowenstein-Jensen, Middlebrook 7H9, or Dubos medium. *M. leprae* is the only *Mycobacterium* species that does *not* grow on at least one type of axenic medium. Of course, one needs to include a control test, such as inoculation into mouse footpads, to ensure that the original preparation did indeed contain viable bacteria.

M. leprae grows in mice, rats, armadillos, and monkeys and produces a characteristic pattern of proliferation and histopathologic changes in each animal (for details, see Shepard, 1986). Hence, growth characteristics can be used for identification purposes. For practical and economic reasons, one usually starts by analyzing growth in mice and then proceeds onto other animal models only as warranted. A key step in this test is careful observation of histopathologic changes. For example, *M. leprae* is the only *Mycobacterium* species to invade peripheral nerves and such invasion is prominent in the later stages of an *M. leprae* infection in the thymectomized-irradiated mouse and in the armadillo. Hence, observation of acid-fast bacilli in nerves is a good indication that the organism is *M. leprae*.

Biochemical Tests

Among the mycobacteria, *M. leprae* has a unique pattern of drug susceptibilities (Shepard, 1971;

Shepard et al., 1983; Hastings and Franzblau, 1988). Thus, one could confirm a presumptive identification by measuring drug susceptibility in: 1) inhibition of in vivo growth in the mouse footpad (Shepard, 1971); 2) inhibition of growth in macrophage culture (Mittal et al., 1983; Ramasesh et al., 1987); or 3) effect of the drug on PGL-I synthesis, palmitate oxidation, or ATP generation in bacilli maintained in a synthetic medium (Franzblau, 1988; Franzblau and Hastings, 1987; Franzblau et al., 1987). Note that the bacilli do not multiply in the systems used by Franzblau and colleagues.

Several identification tests are based on the observation that *M. leprae* contains components, structures, enzymes, and antigens that apparently are not present in any of the other *Mycobacterium* species. For example, enzymatic activities that are apparently unique to *M. leprae* (among the mycobacteria) include the ability to oxidize 3,4-dihydroxyphenylalanine (DOPA) and the synthesis of phenolic glycolipid I (PGL-I). DOPA-oxidase activity can be measured in vitro by following the conversion of DOPA to the pigmented product indole-5,6-quinone (Prabhakaran and Kirchheimer, 1966). This test is not entirely specific for *M. leprae*, since some non-acid-fast bacteria and, more importantly, some mammalian tissues have similar oxidase (phenolase) activities (Prabhakaran, 1967). PGL-I biosynthesis can be followed by measuring the incorporation of ^{14}C -palmitate into PGL-I in an *M. leprae*/macrophage co-culture system (Ramasesh et al., 1987) or in bacilli maintained in a synthetic medium (Franzblau and Hastings, 1987). Since PGL-I is unique to *M. leprae*, this assay is particularly useful. Also, characterization of the susceptibility of the in vitro reaction to various drugs can help confirm the identification.

Characteristic biochemical components of *M. leprae* include: 1) peptidoglycan that contains glycine instead of L-alanine in the linking peptide (Draper, 1976); 2) a GC content of 56 mol% as opposed to GC contents of 65–70 mol% for the other *Mycobacterium* species (Clark-Curtiss et al., 1985; Imaeda et al., 1982; Wayne and Gross, 1968); 3) PGL-I. However, other mycobacteria (e.g., *M. tuberculosis*) have structurally similar phenol-phthiocerol triglycosides (Brennan, 1983; Chatterjee et al., 1989; Daffe et al., 1988; Hunter and Brennan, 1981); and 4) specific mycolic acids (Draper, 1976). Analysis of the mycolic acids may be particularly informative since the high pressure liquid chromatography (HPLC) pattern of mycolic acids produced following alkaline methanolysis seems to be unique for each species of *Mycobacterium*. Indeed, Butler and Kilburn (1988) have devised a relatively simple and rapid scheme based on such HPLC

patterns for identifying many of the *Mycobacterium* species.

Immunological Tests

Several antigens (or epitopes?) also appear to be uniquely present in *M. leprae* (reviewed in Gaylord and Brennan, 1987). Particularly useful reagents are monoclonal antibodies directed against the *M. leprae*-specific oligosaccharide of PGL-I (Mehra et al., 1984; Young et al., 1984). Such antibodies have been shown to react only with *M. leprae* and have been used in the serodiagnosis of leprosy (Cho et al., 1986; Koster et al., 1987; Sanchez et al., 1986; Young et al., 1985). Several other monoclonal antibodies are also available that react with other targets that appear to be *M. leprae*-specific (reviewed in Gaylord and Brennan, 1987). One could also assay the reactivity of the unknown with T-cell clones that are directed against *M. leprae*-specific components. Other potential immunological tests include fluorescent-antibody stains (Abe et al., 1980), immunodiffusion assays (Payne et al., 1982), immunoprecipitation assays (Harboe et al., 1978), and the ability to induce a delayed type hypersensitivity reaction in infected individuals similar to that induced by authentic *M. leprae* preparations, e.g. lepromin (Shepard and Guinto, 1963). In any immunological test, one should be aware that *M. leprae* does contain many antigens and epitopes that are cross-reactive with antigens found in one or more of the other *Mycobacterium* species as well as antigens that are cross-reactive with organisms that are evolutionarily very distant, including humans.

Genetic Tests

One can measure the relatedness of two organisms by determining the degree of hybridization between genomic DNAs from the two organisms (Brenner, 1989). Cells from the same species have DNA homologies of greater than 70% and a difference in melting temperature of $<5^\circ\text{C}$. Such genomic DNA:DNA hybridization studies have been reported for *M. leprae* and a variety of other *Mycobacterium* species. *M. leprae* shows little if any homology with the other mycobacteria (Athwal et al., 1984; Grosskinsky et al., 1989). Thus, this sort of test might be useful in identifying *M. leprae*. Unfortunately, such genomic DNA hybridization studies require fairly large amounts of DNA (10–100 μg , 10^9 – 10^{10} bacilli), not easily obtained for a nonaxenically cultivable bacterium.

One way to circumvent the need for such large amounts of DNA is to use a labelled (e.g., radioactive) nucleic acid probe to assess DNA homologies (reviewed in Tenover, 1989). Using

labelled probes, one can reduce the number of organisms needed for analysis to 10^5 to 10^6 . Potential hybridization probes (nucleotide sequences that hybridize only with *M. leprae* nucleic acids) for *M. leprae* have been identified and cloned into *E. coli*, which allows easy production of large amounts of the probes. Of particular interest is the work of Clark-Curtiss and colleagues (Clark-Curtiss and Docherty, 1989; Grosskinsky et al., 1989), who have identified a sequence that is present in about 19 copies in the *M. leprae* genome and is not present in other mycobacteria. Using this sequence as a probe and purified DNA, they were able to detect as few as 4×10^3 genome equivalents of *M. leprae* DNA. Furthermore, they were able to detect homologous sequences in skin biopsy samples from lepromatous leprosy patients, which is of potential clinical importance. Incidentally, the *M. leprae* genome appears to be very stable with respect to this sequence in that all *M. leprae* isolates (from patients, armadillos, and monkeys) examined to date have identical hybridization patterns, with the exception of a single difference found in only one of the armadillo isolates (Clark-Curtiss and Walsh, 1989). This observation suggests that the probe should be capable of detecting all *M. leprae* isolates.

Several research groups are currently exploring the potential use of gene amplification techniques such as the polymerase chain reaction (PCR) to detect and identify *M. leprae*. In this technique, one uses oligonucleotide primers to direct the amplification of a particular nucleotide sequence via a bidirectional polymerase cascade reaction (Guatelli et al., 1989; Mullis and Faloona, 1987). The specificity of the reaction is determined by the choice of primers. In some preliminary studies, we have used oligonucleotide primers corresponding to various regions of the gene encoding the 65-kilodalton(kDa) antigen (B. B. Plikaytis and T. M. Shinnick, unpublished observations). Primers representing sequences unique to *M. leprae* direct the amplification of the gene from *M. leprae* but not from the other *Mycobacterium* species tested. The potential power of this technique can be demonstrated by two results. First, using these primers, we can specifically detect as few as 10 copies of the *M. leprae* 65-kDa antigen gene in a sample containing 10^6 copies of the *M. tuberculosis* 65-kDa antigen gene. Second, using crude lysates of *M. leprae*, grown in mouse footpads, we can detect a positive signal in a sample containing as few as 20 bacilli.

These results indicate that the gene amplification technology can be used to amplify specifically sequences from *M. leprae*. Importantly, without optimizing the system, we were able to detect the equivalent of as few as 20 bacilli in a

sample—a sensitivity much better than that of the currently available clinical tests. However, much work needs to be done before we can truly assess the potential clinical impact of this technology for leprosy. For example, among other things the system must be optimized with respect to: 1) target sequence and primers; 2) recovery of bacilli and isolation of DNA; 3) reaction conditions; and 4) detection systems. Nonetheless, the degree of sensitivity and specificity displayed by the primers described above is quite encouraging for the potential use of this technology in the rapid detection of small numbers of mycobacteria in clinical specimens and the positive identification of the organism as *M. leprae*.

Summary

Although much has been learned about the structure and composition of the *M. leprae* bacillus, the challenge for the identification and characterization of *M. leprae* still lies with the inability to propagate the organism outside of animal hosts. Until a suitable axenic culture system is developed, one must rely on animal models, hence making identification and characterization quite laborious. Fortunately, there are methods and procedures on the horizon for the analysis of very small numbers of bacilli (PCR) and for the analysis of the metabolic activity of bacilli (Franzblau and Hastings, 1987). These advances will probably facilitate the identification of organisms as *M. leprae* and the characterization of relevant biochemical traits.

The Genus *Arthrobacter*

DOROTHY JONES AND RONALD M. KEDDIE

Conn (1928) described a group of bacteria, extremely numerous in certain soils, which were unusual in that they appeared as Gram-negative rods in young cultures and as Gram-positive cocci in older cultures. For these bacteria, Conn (1928) created the species *Bacterium globiforme*, which, as *Arthrobacter globiformis*, was later to become the type species of the genus *Arthrobacter*. The abundance in soil of bacteria similar to Conn's organism, and of other coryneform bacteria, was confirmed later by Jensen (1933, 1934) and Topping (1937, 1938), who, however, referred to them as soil corynebacteria, and by Taylor and Lochhead (1937), who used the name *Bacterium globiforme*. Jensen (1934) considered that these soil bacteria should be classified in the genus *Corynebacterium* because of their morphological resemblance to corynebacteria of animal origin. However, Conn (1947) vigorously opposed this view and created the genus *Arthrobacter* (by reviving an old name), with *A. globiformis* as the type species and with two of Jensen's soil corynebacteria as additional species (Conn and Dimmick, 1947).

In addition to their characteristic morphology and staining reactions, members of the genus *Arthrobacter* were originally described as being highly aerobic, nutritionally nonexacting, and capable of liquefying gelatin slowly (Conn and Dimmick, 1947). These features were chosen mainly to distinguish *Arthrobacter* from *Corynebacterium* as represented by *C. diphtheriae* and similar animal parasitic species. However, because of its poor circumscription (see Gibson, 1953; Jensen, 1952), the genus *Arthrobacter* was not widely accepted until it was included as a member of the family Corynebacteriaceae in the seventh edition of *Bergey's Manual of Determinative Bacteriology* (Breed et al., 1957). But by that time, the genus had been extended to include the two nutritionally exacting species *A. terregens* (Lochhead and Burton, 1953) and *A. citreus* (Sacks, 1954), and shortly afterwards two others were added (Lochhead, 1958a). Indeed, one of Conn's strains of *A. globiformis* was shown subsequently to require biotin for growth (Chan and Stevenson, 1962; Morris, 1960). Thus the concept had developed of *Arthrobacter* as a genus of soil bacteria whose major distinguishing feature was a growth cycle in which the irregular rods in young cultures were replaced by coccoid forms in older cultures; these coccoid forms, when transferred to fresh medium, produced outgrowths ("germinated") to give irregular rods again, and so the cycle was repeated (Fig. 1).

This dependence on morphological features and habitat in the circumscription led to a great deal of confusion in the classification of the genus *Arthrobacter* and thus created considerable problems in the identification of new isolates as arthrobacters. Thus, isolates from soil and, more especially,

those from other habitats have frequently been referred to in the literature as arthrobacters on the basis of morphological features alone, even though they were not necessarily similar to *A. globiformis* in other respects.

It was not surprising that when representatives of the genus were examined by more modern taxonomic methods such as numerical taxonomy (Jones, 1978), various chemotaxonomic techniques (Bowie et al., 1972; Keddie and Cure, 1977, 1978; Minnikin et al., 1978b; Schleifer and Kandler, 1972), and determinations of DNA base ratios (see Skyring and Quadling, 1970; Skyring et al., 1971), it was found to be heterogeneous.

The genus *Arthrobacter* as defined in the eighth edition of *Bergey's Manual* (Keddie, 1974) was heterogeneous, as was noted by Keddie and Jones (1981) in the first edition of *The Prokaryotes*. They referred to *Arthrobacter* in this broad sense as *Arthrobacter sensu lato* (Keddie and Jones, 1981). In *Bergey's Manual of Systematic Bacteriology* (Keddie et al., 1986), the genus was limited to those species which, like the type, *A. globiformis*, contain lysine as the cell wall diamino acid, i.e., *Arthrobacter sensu stricto* (Keddie and Jones, 1981). Thus some species formerly considered to be arthrobacters (Keddie, 1974) have now been removed from the genus.

The two species formerly named *A. terregens* and *A. flavescens*, which contain ornithine as the cell wall diamino acid (Schleifer and Kandler, 1972; Keddie and Cure, 1977), have been transferred to the genus *Aureobacterium* as *Aur. terregens* and *Aur. flavescens* (Collins et al., 1983). The species *Arthrobacter radiotolerans* has now been transferred to the new genus *Rubrobacter* as *R. radiotolerans* (Suzuki et al., 1988).

Although now resolved, the position of the two species *A. simplex* and *A. tumescens* has been more problematical. They were shown by Cummins and Harris (1959) to differ from *A. globiformis* in containing LL-diaminopimelic acid (LL-A₂pm) as the cell wall diamino acid, and many other taxonomic differences were detected subsequently (see Keddie et al., 1986, for further details). In the case of *A. simplex*, 16S rRNA cataloging studies showed this species to be only distantly related to *A. globiformis* (Stackebrandt et al., 1980). Conversely, 5S rRNA sequencing indicated that *Pimelobacter simplex* (*A. simplex*—see below) clearly belonged to an "*Arthrobacter*—*Micrococcus*—*Cellulomonas*" subgroup of the coryneform bacteria (Park et al., 1987). While there was general agreement that *A. simplex* and *A. tumescens* should be removed from *Arthrobacter*, there was disagreement about where they should be accommodated. Suzuki and Komagata (1983) created the genus *Pimelobacter* for the LL-A₂pm-containing coryneform bacteria and distinguished three species by use of DNA-DNA base-pairing techniques. The first species, *Pimelobacter simplex*, contained most strains of *A. simplex* (and also strains named "*Brevibacterium*

Fig. 1. *Arthrobacter globiformis* (ATCC 8010) grown on medium EYGA at 25°C; the inoculum was of coccoid cells as shown in (d). (a) After 6 h, showing outgrowth of rods from coccoid cells. (b) After 12 h. (c) After 24 h. (d) After 3 days. Bars = 10 µm.

lipolyticum”), the second, *P. tumescens*, was for strains formerly called *A. tumescens*, and a third species, *P. jensenii*, was created for a single strain originally identified as an *A. simplex* strain (Gundersen and Jensen, 1956). The same authors also concluded from their DNA homology studies that *A. simplex* and *A. tumescens* were only distantly related to *Nocardioides albus*, a nocardioform organism. However, O’Donnell et al. (1982) considered that *A. simplex* (but not *A. tumescens*) closely resembled *Nocardioides* species in chemotaxonomic (particularly lipid) characters and proposed that it be transferred to that genus as *Nocardioides simplex*. This view received support from other studies (reviewed by Keddie et al., 1986). In an attempt to resolve the problem, Collins et al. 1989 made a comparative study of the 16S rRNA from the type strains of *Nocardioides albus*, *N. luteus*, *Pimelobacter simplex*, *P. tumescens*, and *P. jensenii* by reverse transcriptase sequencing and compared the results with those from 18 previously studied actinomycetes from 14 different genera. The study confirmed the reclassification of *P. (Arthrobacter) simplex* in the genus *Nocardioides* as *N. simplex* as proposed by O’Donnell et al. (1982) and also showed that *P. jensenii* should be transferred to that genus as *N. jensenii* (Collins et al., 1989). However, *P. (Arthrobacter) tumescens* was so distinct from all the other actinomycete taxa that Collins et al. (1989) proposed its reclassification in a new genus, *Terrabacter*, as *T. tumescens*. The taxonomic status of the single strain of the species *A. duodecadis* remains unresolved. Details of this and some other species named *Arthrobacter*, but now excluded from the genus, are given by Keddie et al. 1986 and for *A. siderocapsulatus* and *A. viscosus* by Collins (1986).

However, Collins (1986) has shown that the lipid composition of “*A. sialophilus*” (Tanenbaum and Flashner, 1977) and the phytopathogen *Agrobacterium pseudotsugae* is con-

sistent with their being members of *Arthrobacter* sensu stricto (Keddie and Jones, 1981), but no formal proposal has been made to include them in the genus.

As presently circumscribed, the genus *Arthrobacter* contains two “groups of species” referred to as the *A. globiformis/A. citreus* group and the *A. nicotianae* group. These groups differ in their peptidoglycan structure, teichoic acid content, and lipid composition (see “Further Identification of Arthrobacters” and Tables 2 and 3 for details). It has been suggested that the genus should be restricted to those bacteria that exhibit the characteristics of the *A. globiformis/A. citreus* group (Minnikin et al., 1978a; Collins and Kroppenstedt, 1983). However, on the basis of DNA-DNA homology studies of representative arthrobacters (Stackebrandt and Fiedler, 1979) and later 16S rRNA cataloging studies, Stackebrandt et al. (1983) concluded that the genus *Arthrobacter* contained two “nuclei,” one represented by the *A. globiformis/A. citreus* group of species and the other by the *A. nicotianae* group. This view was adopted by Keddie et al. (1986) and is the one accepted here.

The results of 16S rRNA cataloging studies (Stackebrandt et al., 1980; Stackebrandt and Woese, 1981) indicate that the genus *Arthrobacter* is related to the other coryneform genera, *Aureobacterium*, *Cellulomonas*, *Curtobacterium*, and *Microbacterium*, and is more distantly related to *Brevibacterium*. All of these genera are members of the high GC “actinomycete” branch of the Gram-positive eubacteria (Stackebrandt and Woese, 1981). The studies of Stackebrandt et al. (1980) also showed that on a phylogenetic basis the *Arthrobacter* species could not be separated from members of the genus *Micrococcus*. While accepting that the genera *Arthrobacter* and *Micrococcus* are very closely related phylogenetically, we treat them here as distinct taxa for practical purposes.

Table 1. Some characteristics^a of the *Arthrobacter* species having peptidoglycans of the A3 α variation^b and MK-9 (H₂)^c as major menaquinones—the *A. globiformis*/*A. citreus* group.^{d,e}

^aMost species are represented only by their type strain; therefore, the range of variation within the species is not known. For this reason, data on carbon source utilization tests are not included although studies on a wider range of strains may prove them to be useful. See section on "Soil and Similar Habitats" for a list of near-universal substrates. There are conflicting reports in the literature about the responses of the type strains of some species in some common tests such as nitrate reduction, urea hydrolysis, etc., and therefore these data have been omitted. Other data are from original and/or revised descriptions of species and from Keddie et al. (1966), Yamada and Komagata (1972), and Cure and Keddie, and Robertson and Keddie, unpublished observations.

Habitats of *Arthrobacter*

In many ecological studies, isolates have been identified as arthrobacters or described as "arthrobacter-like" simply because they showed the rod-coccus growth cycle and the staining reactions characteristic of the genus. Although the sequence of morphological changes that occurs during the growth cycle is an important distinguishing feature of the genus, it does not occur exclusively in arthrobacters. For example, it is also seen in the genus *Brevibacterium* and in at least some members of the genus *Rhodococcus*. Accordingly, some of the strains described as arthrobacters in the literature cited below may belong to other morphologically similar taxa, especially if they are isolates from habitats other than soil.

Soil and Similar Habitats

Many studies have shown that bacteria of the genus *Arthrobacter* form a numerically important

fraction of the indigenous bacterial flora of soils from different parts of the world; they are sometimes the most numerous, single bacterial group recorded in aerobic plate counts (Hagedorn and Holt, 1975b; Holm and Jensen, 1972; Lowe and Gray, 1972; Mulder and Antheunisse, 1963; Skyring and Quadling, 1969; Soumare and Blondeau, 1972). However, both the numbers and the proportions of arthrobacters in "total" counts decrease with increasing soil acidity (Hagedorn and Holt, 1975b; Lowe and Gray, 1972). Among the explanations advanced for their numerical predominance are their extreme resistance to drying (Boylen, 1973; Chen and Alexander, 1973; Labeda et al., 1976; Mulder and Antheunisse, 1963; Robinson et al., 1965) and to starvation (Boylen and Ensign, 1970; Boylen and Mulks, 1978; Zevenhuizen, 1966), factors important in the survival of microorganisms in soil (Gray, 1976). However, the nutritional versatility of the commonly occurring species undoubtedly also plays a part (see below).

Both psychrophilic and psychrotrophic strains of the genus were reported to be the most abun-

Table 3. Characters^a differentiating *Arthrobacter* from similar genera which either have a rod-coccus growth cycle or have lysine as the cell wall diamino acid.^b

Formerly *A. simplex*.

Formerly *A. tumescens*.

dant and active bacteria in subterranean cave silts (Gounot, 1967), and they also occur in glacier silts (Moiroud and Gounot, 1969). The genus was also represented among isolates from oil brines raised from soil layers some 200–700 m deep (Iizuka and Komagata, 1965). *Arthrobacters* capable of dissolving aluminium silicates were reported to be common on “karst” rocks, and most were considered to be capable of dinitrogen fixation (Smyk, 1970; Smyk and Ettlinger, 1963). Members of the genus have also been implicated in the growth of manganese nodules in the sea (Ehrlich, 1963, 1968).

There is now much evidence that the predominant soil arthrobacters can use a wide and diverse range of organic substrates as sole or principal sources of carbon and energy (Hagedorn and Holt, 1975a; Keddie, 1974). This nutritional versatility is characteristic of those species which do not require vitamins or other organic growth factors or which require only biotin. Most species now recognized, including *A. globiformis* and new isolates from soil, belong to this nutritional category, with *A. citreus* (type strain) being a notable exception. The detailed carbon nutrition of representatives of a number of species of soil arthrobacters together with 26 unnamed isolates, mainly from soil, was examined by J. D. Owens and R. M. Keddie and G. L. Cure and R. M. Keddie (unpublished observations quoted

in Keddie et al., 1986). The following substrates were utilized by some 90% or more of the strains tested: D-xylose, D-glucose, D-mannose, D-galactose, D-fructose, cellobiose, maltose, trehalose, sucrose, raffinose, melezitose, D-gluconolactone, salicin, acetate, propionate, pentanoate, heptanoate, succinate, fumarate, DL-lactate, DL-malate, citrate, pyruvate, oxaloacetate, glycerol, mannitol, *m*-hydroxybenzoate, *p*-hydroxybenzoate, uric acid, glycine, L- α -alanine, D- α -alanine, L-isoleucine, L-threonine, L-lysine, L-arginine, L-aspartate, L-glutamate, L-phenylalanine, L-tyrosine, L-proline, L-histidine, 1,4-butanediamine, agmatine, tyramine, betaine, sarcosine, and creatine. *A. citreus* (type strain) is less nutritionally versatile than the species mentioned above (Keddie, 1974). Other studies have demonstrated the ability of arthrobacters to utilize aromatic compounds (Stevenson, 1967) and nucleic acids and their degradation products (Antheunisse, 1972). The frequent recovery of *Arthrobacter* species from enrichment cultures in which various diverse, organic compounds are supplied as sole carbon sources in simple, mineral media is further evidence of this nutritional versatility. Such compounds include nicotine (Giovannozzi-Sermanni, 1959; Keddie et al., 1966; Sgueros, 1955), puromycin amino-nucleoside (Greenberg and Barker, 1962), 2-hydroxypyridine (Ensign and Ritten-

berg, 1963; Kolenbrander et al., 1976), *n*-alkanes (Klein et al., 1968), lower alcohols (Akiba et al., 1970), choline (Kortstee, 1970), picolinic acid (Tate and Ensign, 1974), and squalene (Yamada et al., 1975).

Arthrobacters have also been shown to degrade herbicides such as disodium endoxo-hexahydrophthalate ("Endothal") (Jensen, 1964) and 2,4-dichlorophenoxyacetate (Cacciari et al., 1971; Loos et al., 1967; Sharpee et al., 1973). Others degrade pesticides, usually by cometabolism, e.g., "diazinon" (Sethunathan and Pathak, 1971) and *m*-chlorobenzoate, the central molecule in many pesticides (Horvath and Alexander, 1970).

Fish and Other Similar Habitats

Coryneform bacteria appear to be common on fish (both marine and freshwater) and on some other seafoods. Many are morphologically similar to arthrobacters (and to *Brevibacterium*) and are frequently referred to by that name. Thus "arthrobacters" have been reported to occur in shark spoilage (referred to as *Corynebacterium globiformis* and *C. helvolum*; Wood, 1950), eviscerated freshwater fish (Roth and Wheaton, 1962), fish-pen slime (Chai and Levin, 1975), and Pacific shrimp (Lee and Pfeifer, 1977). Sieburth (1964) reported the isolation of an *Arthrobacter* species from sea water.

However, in the few cases in which coryneform isolates from fish have been examined by suitable modern methods, their relationship to *Arthrobacter* has proved to be much more remote than has been inferred from their morphological similarity, and most, if not all, of them belong to other taxa (see Bousfield, 1978; Crombach, 1974a, 1974b).

Sewage and Similar Habitats

Bacteria identified as *Arthrobacter* species have been isolated from sewage (Nand and Rao, 1972) and from "brewery sewage" (Kaneko et al., 1969). Arthrobacters physiologically similar to those from soil were common in dairy-waste activated sludge (Mulder and Antheunisse, 1963) and were considered to play an important role in the process (Adamse, 1968). A number of the activated-sludge strains were reported by the above authors to decompose phenol. However, subsequent examination of four of these phenol-decomposing strains using chemotaxonomic methods revealed that they were members of the "rhodochrous" taxon (*Rhodococcus*) (Keddie and Cure, 1977). Similarly, although Schefferle (1966) considered that the predominant coryneform bacteria in poultry deep litter could be

placed in the genus *Arthrobacter*, only one of seven of these litter strains subsequently examined by Keddie and Cure (1977) was considered to be a legitimate *Arthrobacter* species. Although many coryneform isolates from aerated, animal-manure slurries are similar in morphology to *Arthrobacter*, only 1 of 16 such isolates examined was identified as *A. globiformis*; most of the remainder were considered to be "rhodochrous" strains, and a few were similar to *Brevibacterium linens* (Keddie and Cure, 1977).

Such examples clearly illustrate that new isolates should not be assigned to the genus *Arthrobacter* on the basis of morphology and conventional features alone.

Other Habitats

Coryneform bacteria seem to be relatively common on the aerial surfaces of plants (Austin et al., 1978; Keddie et al., 1966; Mulder et al., 1966) but few have been shown to be legitimate arthrobacters. However, "arthrobacter-like" organisms have been isolated from frozen vegetables (Splittstoesser et al., 1967). Also, two of a number of strains isolated from cauliflower by Lund (1969) were later identified as *A. globiformis* strains by Keddie and Cure (1977), but it is possible that they were contaminants from soil rather than indigenous plant bacteria. However, the organism formerly called *Corynebacterium ilicis*, a pathogen of American holly (Mandel et al., 1961), has been shown to be a legitimate *Arthrobacter* species and has now been transferred to that genus as *A. ilicis* (Collins et al., 1981). The type strain of *A. protophormiae* (formerly *Brevibacterium protophormiae*; Lysenko, 1959) was isolated from an insect, *Protophormia terraenovae*, but other strains were isolated from soil (see Keddie et al., 1986).

Arthrobacters were reported to be numerous in commercial preparations of liquid eggs, probably as a result of contamination from the shells, but they were rarely isolated from turkey giblets (Kraft et al., 1966). Arthrobacters do not appear to have been isolated from clinical sources.

Isolation of Arthrobacters

Arthrobacters have normally been isolated from soil and similar habitats by plating on suitable nonselective ("total count") media, and then picking from a large, random selection of colonies, and identifying as arthrobacters those isolates that show a rod-coccus growth cycle (Holm and Jensen, 1972; Lowe and Gray, 1972; Skyring and Quadling, 1969). This method is only suitable for habitats such as soil in which arthro-

bacters form an appreciable proportion of the aerobic cultivable population. A further extension of this technique was introduced by Mulder and Antheunisse (1963), who devised what was essentially a method for screening isolates picked from a nonselective medium for those that showed the typical rod-coccus growth cycle of arthrobacters (see also Mulder et al., 1966; Veldkamp, 1965). Hagedorn and Holt (1975b) devised a selective medium said to be suitable for the enumeration of arthrobacters in soil. Thus, when nine different soils were plated on this medium, an average of 74% of the colonies that developed were identified as arthrobacters, and the numbers were similar to those estimated from counts on a nonselective medium (Hagedorn and Holt, 1975b).

However, if identification of the isolates is based only, or largely, on the provision of a rod-coccus growth cycle as was the case in the studies quoted, then bacteria from other genera such as *Brevibacterium* and *Rhodococcus* may be mistaken for arthrobacters. If, however, isolates are screened for the presence of lysine in the cell wall by using a rapid method of cell wall analysis, then this problem is overcome.

As noted above, a number of *Arthrobacter* species have been isolated from enrichment cultures using a variety of organic substrates as sole carbon and energy sources in mineral salts media. However, the primary purpose of such enrichments was not to isolate arthrobacters but to obtain isolates capable of utilizing the particular substrates studied. Accordingly, it is not possible to assess the value of these enrichment methods for the isolation of particular strains of arthrobacters.

Nonselective Media for Isolation of Arthrobacters

The aim of this approach is to use media and conditions of incubation which give the maximum possible counts of soil bacteria capable of growth under aerobic conditions. The media used must therefore contain sufficient amounts of all the organic growth factors and mineral constituents required to provide the diverse nutritional requirements of the indigenous soil bacteria (see Lochhead, 1958b). But, at the same time, media must be sufficiently poor in carbon and energy sources to limit the size of colonies, thereby minimizing antagonistic effects between the components of the population. Various modifications of soil extract agar have been the media most widely used. Lochhead, who pioneered the use of such media, strongly advocated the use of soil extract agar without other additions (Lochhead and Burton, 1956), but for some soils, addition of low concentrations of yeast extract

and glucose can give higher counts (Jensen, 1968). Examples of both kinds of soil extract agars are given below. If necessary, the growth of fungi may be suppressed by incorporating the antibiotics nystatin (50 µg/ml) and cycloheximide (50 µg/ml) in the medium (Williams and Davies, 1965). Other factors important in plating soil samples have been discussed by Jensen (1968). The more important of these are: 1) the soils should be examined within a few hours of sampling; 2) the primary dilution should be dispersed by using a laboratory blender but avoiding heating; 3) a suitable diluent should be used (see below); and 4) plates should be incubated at 25°C for a minimum of 2 weeks.

Jensen (1968) recommends Winogradsky's standard salt solution as a diluent. It has the following composition (Holm and Jensen, 1972):

Winogradsky's Standard Salt Solution

K ₂ HPO ₄	0.25 g
MgSO ₄	0.125 g
NaCl	0.125 g
Fe ₂ (SO ₄) ₃	0.0025 g
MnSO ₄	0.0025 g
Deionized water	1 liter

Adjust pH to 6.5–6.7.

Soil extract and dilute peptone solutions (0.05–0.1%, wt/vol) have also been used successfully but one-fourth-strength Ringer's solution, physiological saline, and tap water are unsuitable (Jensen, 1968). In this context, Owens and Keddle (1969) noted that a chelated mineral salts solution which they devised, but without (NH₄)₂SO₄ (mineral base E-N), was a suitable diluent for coryneform bacteria. Mineral base E-N gave slightly better survival of *Arthrobacter globiformis* than a simple salts solution gave and was markedly superior to traditional diluents such as one-fourth-strength Ringer's solution or physiological saline. The preparation of mineral base E-N was described by Cure and Keddle (1973).

Isolation of Arthrobacters Using Soil Extract Agar

Soil Extract (Lochhead and Burton, 1957)

To prepare the soil extract, add 1 kg of soil to 1 liter of tap water and autoclave at 121°C for 20 min; filter and restore volume to 1 liter with tap water. A fertile garden soil usually gives the best results (Jensen, 1968).

Soil Extract Agar for Isolating Arthrobacters (Lochhead and Burton, 1957)

Soil extract (see above), 1 liter; K₂HPO₄, 0.2 g; agar, 15 g; final pH 6.8. Autoclave at 121°C for 20 min. Colonies are picked into tubes of soil extract semisolid medium: soil extract, 1 liter; K₂HPO₄, 0.2 g; yeast extract, 1 g; agar, 3 g; final pH 6.8. Autoclave at 121°C for 20 min.

Soil Extract Agar for Isolating Arthrobacters (Holm and Jensen, 1972)

Soil extract (see above)	400 ml
Tap water	600 ml
Glucose	1 g
Peptone	1 g
Yeast extract	1 g
K ₂ HPO ₄	1 g
Agar	20 g

Adjust pH to 6.5–6.7.

After sterilization and immediately before use, a filter-sterilized solution of cycloheximide is added to the medium to give a final concentration of 40 mg/liter. Before pouring plates, a layer of sterile agar is poured in the bottom of the plates and allowed to solidify. This prevents colonies from spreading between the agar and the bottom of the petri dishes. Colonies are picked onto slants of the same medium.

Isolation and Enumeration of Arthrobacters from Soil (Mulder and Anthéunisse, 1963)

Dilutions are prepared and plates poured using the following “poor” medium (g/liter tap water):

Ca(H ₂ PO ₄) ₂	0.25
K ₂ HPO ₄	1.0
MgSO ₄ · 7H ₂ O	0.25
(NH ₄) ₂ SO ₄	0.25
Casein	1.0
Yeast extract	0.7
Glucose	1.0
Agar	10.0

Adjust pH to 6.9–7.0.

After incubation for 5 days at 25°C, colonies are counted and a large number are transferred to agar slants of the same composition. The slants are incubated for 7 days at 25°C and then examined microscopically. Colonies that consist of coccoid cells are then transferred to a “rich” medium containing (% wt/vol): yeast extract, 0.7; glucose, 1.0; agar, 1.0. The cultures are examined in the exponential phase of growth (usually not more than 24 h), and those showing “germinating” cocci and irregular rods are considered to be “arthrobacters.”

Obviously, in the sense used by Mulder and Anthéunisse (1963), the term “arthrobacters” refers to all bacteria that show the rod-coccus growth cycle of the genus *Arthrobacter*.

Isolation of Arthrobacters by Selective Media**Selective Medium of Hagedorn and Holt (1975b)**

In this method, plate counts are made by spreading 0.1-ml amounts of suitable dilutions over the surface of sterile medium in petri dishes. Peptone solution (0.5%, wt/vol) was used as the diluent by Hagedorn and Holt (1975b). The selective medium has the following composition:

Trypticase soy agar (BBL)	0.4%
Yeast extract (Difco)	0.2%
NaCl	2.0%
Cycloheximide	0.01%
Methyl red (Harleco)	150 µg/ml
Agar	1.5%

The methyl red is filter-sterilized and added aseptically to the autoclaved, cooled medium. The medium is adjusted to the pH of the particular soil being examined.

The selective properties of the medium are said to be unaffected by pH values in the range 5.0–8.5. After incubation for 10 days at 25°C, the plates are counted. Colonies are transferred to slants of trypticase soy agar containing 0.2% yeast extract and examined microscopically for the possession of a morphological growth cycle as described in *Bergey's Manual* (Keddie, 1974). From the results obtained, the authors concluded that 78% of the counts on the selective medium was a suitable approximation of the arthrobacter counts for the soils studied. The authors state that:

The combination of actidione [cycloheximide] at 0.01% and NaCl at 2.0% effectively inhibited all fungi and most streptomycetes, nocardia, and Gram-negative bacteria. The methyl red at 150 µg/ml inhibited other Gram-positive bacteria (bacilli and micrococci) but did not affect the arthrobacters. The pH of the medium, between 5.0 and 8.5, did not affect its selectivity, and the combination of trypticase soy agar at 0.4% and yeast extract at 0.2% gave the highest yield of arthrobacters with the addition of the selective ingredients over the other basal media [tested].

The selective medium gave arthrobacter counts several times higher than those on the nutritionally “poor” medium of Mulder and Anthéunisse (1963) for the four soils examined (Hagedorn and Holt, 1975b).

Preservation of Cultures

Stab cultures by loop in TSX semisolid medium (Keddie et al., 1966) or in the soil extract semisolid medium of Lochhead and Burton (1957) (see above) will remain viable for at least three months at room temperature (ca. 20°C) provided they are not allowed to dry out. Cultures may be preserved for longer periods (at least 10 years) by freezing in glass beads at –70°C (Jones et al., 1984). For long-term storage, lyophilization is suitable.

Identification of Arthrobacters

Members of the genus *Arthrobacter* can be recognized by examining the following characters: morphology and staining reactions, oxygen relations, acid production from glucose, and cell wall composition.

The most distinctive feature of arthrobacters is the marked change of form that occurs during the growth cycle on complex media. Stationary phase cultures (usually 2–7 days) are composed entirely or largely of coccoid cells (Fig. 1d)

which, on transfer to fresh complex medium, produce one and sometimes two (or occasionally more) outgrowths that give rise to the irregular rods characteristic of exponential phase cultures (Fig. 1a–c). Some of the cells are arranged in V-formations but more complex angular arrangements may also occur. Cells may show primary branching, but true mycelia (showing secondary branching) are not produced. As growth proceeds, the rods become shorter and are eventually replaced by the coccoid forms characteristic of stationary phase cultures (Fig. 1d). For more detailed accounts of *Arthrobacter* morphology and morphogenesis, see Keddie (1974), Luscombe and Gray (1971), Clark (1972), and Duxbury and Gray (1977). Both rod and coccoid forms are Gram positive, but may decolorize readily, and are not acid-fast. The rods are non-motile or motile by one subpolar or a few lateral flagella. They are obligate aerobes. The mode of metabolism is respiratory, never fermentative; little or no acid is formed from sugars in peptone media. The cell wall peptidoglycan contains lysine as diamino acid.

Additional features include the following: they are catalase-positive. The optimum temperature for growth is 25–30°C, and most *Arthrobacter* species grow in the range of about 10°C–35°C; many strains also grow at 5°C, and a few grow at 37°C. Some obligately psychrophilic isolates with a growth range of about –5°C to 20°C that are considered to be a new species of *Arthrobacter* (“*A. glacialis*”) were described by Moiroud and Gounot (1969). They do not survive heating at 63°C for 30 min in skim milk. They do not hydrolyze cellulose. DNase is produced and gelatin is usually liquefied (Keddie et al., 1986). The GC content of the DNA of most species is in the range of 59–66 mol% but that of *A. atrocyaneus* is higher, at about 70 mol% (see Keddie et al., 1986, for references).

The extent to which the morphology of arthrobacters changes during the growth cycle is markedly influenced by the nutritional status of the medium (see Clark, 1972; Ensign and Wolfe, 1964; Luscombe and Gray, 1971; Veldkamp et al., 1963); therefore, the medium used for morphological studies must be chosen with care (see Cure and Keddie, 1973). Many different media have been used for this purpose and most are based on soil extract (e.g., see Holm and Jensen, 1972; Lochhead and Burton, 1957). However, such media may give inconsistent results because of the variable nature of soil extract and because some mineral components may be precipitated to different extents during preparation. Medium EYGA (Cure and Keddie, 1973) was devised to overcome such problems and has proved to be satisfactory for examining the morphology of arthrobacters.

Cell wall composition may be determined by one of the rapid methods described by Bousfield et al. (1985) in which cell wall material is prepared by alkali treatment of whole cells.

Further Identification of Arthrobacters

Fifteen species of *Arthrobacter* are recognized in *Bergey's Manual of Systematic Bacteriology* (Keddie et al., 1986). Many of these species were created for single strains that possessed some unusual feature, such as a requirement for a particular growth factor, production of an unusual pigment, the ability to utilize a particular substrate, and so on. Accordingly, such species do not necessarily represent the commonly occurring arthrobacters in the habitats from which they were isolated originally and this may in part explain the common experience that many new soil isolates show little resemblance to the named strains used as reference cultures (see Hagedorn and Holt, 1975a; Keddie et al., 1966; Skyring and Quadling, 1969; Seiler et al., 1980). Also, because most species descriptions are based on single strains, the range of variation within the species is not known. Therefore some of the phenotypic features described for a particular species may be strain rather than species characteristics.

Most *Arthrobacter* species now recognized closely resemble the type species *A. globiformis* in a large number of phenotypic (largely nutritional) characters. For this reason they were referred to as the “globiformis” group of arthrobacters in the first edition of *The Prokaryotes* (Keddie and Jones, 1981) and included the species *A. atrocyaneus*, *A. aurescens*, *A. crystallopoietes*, *A. histidinolovorans*, *A. nicotianae*, *A. oxydans*, *A. pascens*, *A. polychromogenes* (considered a subspecies of *A. oxydans* by Stackebrandt and Fiedler, 1979), *A. ramosus*, and *A. ureafaciens*, together with the species *Brevibacterium sulfureum* (now *A. sulfureum*) and the plant pathogen *Corynebacterium ilicis* (now *A. ilicis*) (see Keddie et al., 1986). A list of substrates utilized by 90% or more of single representatives of these species is given in the section on “Soil and Similar Habitats” above. Detailed nutritional data are not available for the two remaining species now recognized, *A. protophormiae* and *A. uratoxydans* (see Keddie et al., 1986). The remaining species, *A. citreus* (type strain only), is readily distinguished from the other species. It has a complex nutrition and requires biotin, thiamin, nicotinic acid, tyrosine, methionine, cystine, and a siderophore such as ferrichrome or mycobactin for growth (Seidman and Chan, 1969). *A. citreus* also utilizes a much more limited range of compounds as sole or major carbon and energy sources than that used by the other species (Keddie et al., 1986). A num-

ber of other strains are listed as *A. citreus* in culture collections but do not have the characteristics of the type strain (ATCC 11624). They were considered to be strains of *A. protophormiae* and *A. uratoxydans* by Stackebrandt et al. (1983) (see Keddie et al., 1986).

However, despite the close phenotypic similarity of most species of *Arthrobacter* (*A. citreus* excepted), two groups within the genus can be distinguished according to their peptidoglycan structure, their lipid composition, and the presence or absence of teichoic acids in the cell walls.

The peptidoglycans of all *Arthrobacter* species contain lysine as diamino acid but more detailed analysis revealed considerable heterogeneity in the cell wall peptidoglycans of the different species. All contain a group A peptidoglycan, i.e., one in which the cross-linkage is between positions 3 and 4 of the peptide subunits. However, the peptide subunits are linked by a number of different interpeptide bridges, depending on the species (Schleifer and Kandler, 1972). Within these numerous different peptidoglycan types, two groups occur, which are referred to as the A3 α and A4 α variations. In the A3 α variation, found in *A. globiformis*, *A. citreus*, and most other species (the "*A. globiformis/A. citreus*" group of Keddie et al., 1986), the interpeptide bridge contains only monocarboxylic acids and/or glycine. In the A4 α variation, however, found in *A. nicotianae* and three other species (the "*A. nicotianae*" group of Keddie et al., 1986), the interpeptide bridge always contains a dicarboxylic acid and in most strains also contains alanine (Schleifer and Kandler, 1972). Thus members of the *A. globiformis/A. citreus* group have peptidoglycans with the A3 α variation (Schleifer and Kandler, 1972) and contain dihydrogenated menaquinones with nine isoprene units [MK-9(H₂)] as their major isoprenoid quinones (Yamada et al., 1976; Collins et al., 1979, 1981; Collins and Jones, 1981). They do not contain teichoic acids in the cell wall (Fiedler and Schäffler, 1987). In contrast, species of the *A. nicotianae* group have peptidoglycans with the A4 α variation (Schleifer and Kandler, 1972; Stackebrandt et al., 1983) and, with the exception of *A. sulfureus*, have unsaturated menaquinones with eight isoprene units (MK-8) as major components, although they also contain substantial amounts of unsaturated menaquinones with nine isoprene units (MK-9) as well (Yamada et al., 1976; Collins and Jones, 1981; Collins and Kroppenstedt, 1983). *A. sulfureus* contains either MK-9 as the major menaquinone (Yamada et al., 1976; Collins et al., 1979) or comparable amounts of MK-9 and MK-10 (Collins and Kroppenstedt, 1983). *A. nicotianae* group strains also differ from *A. globiformis/A. citreus* group strains in possessing cell wall teichoic acids

of the poly(glycero- phosphate) type (Fiedler and Schäffler, 1987). Further differences occur between the two groups in the types of polar lipids they contain. All *A. globiformis/A. citreus* group strains contain diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol. With the exception of *A. citreus*, they also contain several glycolipids (Shaw and Stead, 1971; Kostiw et al., 1972; Collins et al., 1981); *A. citreus* contains fewer glycolipids than the other species contain (Collins and Kroppenstedt, 1983).

The major characteristics of the 11 species of the *A. globiformis/A. citreus* group are listed in Table 1. The characteristics of the four species of the *A. nicotianae* group are listed in Table 2. To distinguish the two groups, the peptidoglycan "variation" may be determined by the rapid screening method described by Schleifer and Kandler (1972) (see also Schleifer and Seidl, 1985). Menaquinone composition may be determined by reverse phase partition thin layer chromatography (TLC) or high performance liquid chromatography (HPLC) (Collins et al., 1980, 1983). Polar lipid patterns may be obtained by two-dimensional TLC analysis of free lipid extracts (Collins et al., 1983). Fiedler and Schäffler (1987) state that *A. nicotianae* group strains may be recognized by testing for the presence of lysine, phosphorus, and glycerol in the cell wall. Further differentiation of the species within the *A. globiformis/A. citreus* group and the *A. nicotianae* group depends in large measure on DNA-DNA hybridization techniques (Fiedler and Stackebrandt, 1979; Stackebrandt et al., 1983). *A. citreus* can readily be distinguished but the remaining species share a high degree of phenotypic similarity, and it is not possible to differentiate them by using phenotypic characters. Those characters which may be of value in differentiation are listed in Tables 1 and 2.

REFERENCE STRAINS. *A. globiformis*, ATCC 8010 (NCIMB 8907). *A. nicotianae*, ATCC 15236 (NCIMB 9458). (Note: NCIMB was formerly NCIB.)

Biochemical and Physiological Properties

All species are catalase positive and probably contain cytochromes, though detailed information on the cytochrome content is not available for all species. The cytochrome composition of *A. globiformis* ATCC 4336 (NCIMB 8602) is *bcaa₃o* when the strain is in the exponential phase of growth but changes to *bcaa₃od* in the stationary phase of growth after the rod-shaped cells become oxygen limited and lose their ability to retain the Gram stain, and coccoid forms

appear (Meyer and Jones, 1973; Jones, 1980). A similar observation was made by Faller and Schleifer (1981) when studying the apparent correlation between morphology and cytochrome content in *A. crystallopoietes*. They noted that rod-shaped cells in exponential phase cultures contained large amounts of cytochrome *aa₃*, but only traces of cytochrome *d*, whereas coccoid cells in early stationary phase cultures contained relatively larger amounts of cytochrome *d* with lower amounts of cytochrome *aa₃*. However, in keeping with the observations of Meyer and Jones (1973) and Jones (1980), they showed that the increase in cytochrome *d* was not correlated with a change in cell morphology but resulted from the oxygen limitation that occurs in late exponential/early stationary phase cultures.

The fragmentary information available on metabolic pathways in *Arthrobacter* species has been reviewed by Krulwich and Pelliccione (1979). In summary, those few species which have been studied fall into two groups with respect to the pathways of carbohydrate dissimilation utilized. In *A. globiformis*, *A. ureafaciens*, *A. crystallopoietes*, and "*A. pyridinolis*," the primary pathways are the Embden-Meyerhof-Parnas (EMP) pathway and, to a smaller extent, the hexose monophosphate (HMP) pathway. In contrast, *A. pascens* and *A. atrocyaneus* use the Entner-Doudoroff and HMP pathways (Krulwich and Pelliccione, 1979). A list of carbon compounds utilized by a number of species as sole or major carbon sources is given in the section on "Soil and Similar Habitats."

Details of the peptidoglycan structure, lipid composition, menaquinone content, and the presence or absence of teichoic acids of the *Arthrobacter* species now recognized are given in the section "Further Identification of Arthrobacters."

Einck et al. (1973) have summarized the data available on bacteriophages active on *Arthrobacter* species.

Arthrobacters may be distinguished from other coryneforms and morphologically similar bacteria which have lysine in the cell wall or which show a rod-coccus growth cycle by the characters listed in Table 3. The differentiation from *Arthrobacter* of some former species now removed from the genus is also given in Table 3.

Biotechnological Potential

Undoubtedly, soil is the most important habitat of bacteria of the genus *Arthrobacter*. Their abundance in soils of various types and in different geographical locations has been amply dem-

onstrated by many investigators. Their numerical predominance, coupled with the nutritional versatility of the commonly occurring species (Hagedorn and Holt, 1975a; Keddle, 1974), suggests that they may be important agents of mineralization in soil and possibly also in some other habitats. Among the compounds reported to be degraded by arthrobacters are certain herbicides and pesticides, as well as a wide range of naturally occurring and synthetic molecules of various degrees of complexity. Other roles that have been ascribed to at least some *Arthrobacter* species are phytohormone production (Barea et al., 1976; Katznelson and Cole, 1965; Rivière, 1963) and dinitrogen fixation (Cacciari et al., 1971; Smyk, 1970; Smyk and Ettlinger, 1963). Putative *Arthrobacter* species have also been reported to lyse yeast cells (Kitamura et al., 1972) and mycelium of *Fusarium roseum*, a carnation-root pathogen (Morrissey et al., 1976; Szajer and Koths, 1973). In the latter case, the *Arthrobacter* strain investigated produced a chitinase and was considered a possible means of biological control of *Fusarium* diseases.

Products of actual or potential commercial importance obtained from *Arthrobacter* species include glutamic acid (Tanaka and Kimura, 1972; Veldkamp et al., 1963) and α -ketoglutaric acid (Tanaka and Kimura, 1972), although it is likely that in some of the examples mentioned the bacteria concerned were not legitimate *Arthrobacter* species (see Keddle and Cure, 1977, 1978). Also, Veldkamp et al. (1966) described a strain of *A. globiformis* that produced large amounts of riboflavin.

In some species of *Arthrobacter*, the morphological changes that occur during the growth cycle have been shown to be subject to nutritional control, and such species have proved to be useful in the study of bacterial morphogenesis (see review by Clark, 1972).

The Genus *Micrococcus*

MILOSLAV KOCUR, WESLEY E. KLOOS AND KARL-HEINZ SCHLEIFER

The genus *Micrococcus* consists of Gram-positive spheres occurring in tetrads and in irregular clusters that are usually nonmotile and nonsporeforming. They are catalase positive and usually aerobic with strictly respiratory metabolism. Most species produce carotenoid pigments. The GC content of the DNA ranges from 65 to 75 mol%. There are nine species recognized in the genus (see later, Table 2). The data on GC content of the DNA, chemical cell wall analysis, and a comparative analysis of 16S rRNA sequences indicate that the genus *Micrococcus* is more closely related to the genus *Arthrobacter* than it is to other coccoid genera such as *Staphylococcus* and *Planococcus* (Keddie, 1974; Kloos et al., 1974; Kocur et al., 1971; Stackebrandt and Woese, 1979). For these reasons it cannot be included with the genera *Staphylococcus* and *Planococcus* in the same family Micrococcaceae. Therefore, both the genus *Micrococcus* and the genus *Arthrobacter* should be regarded as closely related, but separate genera.

Habitats

Mammalian skin is now considered as the primary habitat of micrococci. Micrococci are found more consistently and usually in larger populations on mammalian skin than from other sources (Carr and Kloos, 1977; Glass, 1973; Marples, 1965; Noble and Sommerville, 1974; Kloos et al., 1974, 1976).

Human Skin

Human skin is a rich source of micrococci. It was shown that 96% of 115 people living in 18 different states in the USA carried cutaneous populations of micrococci (Kloos et al., 1974). The percentages of individuals carrying various *Micrococcus* species were as follows: *M. luteus*, 90%; *M. varians*, 75%; *M. lylae*, 33%; *M. nishinomiyaensis*, 28%; *M. kristinae*, 25%; *M. roseus*, 15%; *M. sedentarius*, 13%; *M. agilis*, 4%. Populations of *M. luteus* were usually relatively large and this organism was isolated on the average from 51% of the different skin sites sampled of individuals carrying this species. In a temporal study by Kloos and Musselwhite (1975), it was found that micrococci usually constituted from 1 to 20% of the total aerobic bacteria isolated from

the skin of the head, legs, and arms, but less than 1% of those isolated from the high bacterial density areas of the nares and axillae. In the same temporal study, 80% of the individuals carried micrococci on the head, legs, and arms for at least 1 year. Where strain (or clonal) populations could be resolved, it was determined that certain strains of *M. luteus*, *M. varians*, *M. kristinae*, and *M. sedentarius* persisted on specific individuals up to 1 year, which strongly suggested a resident status. Several strains of *M. luteus* that were monitored for longer periods persisted for up to 2½ years. Most strains appeared to be more transient and were isolated once or more for periods up to 6 months. In another temporal study of the micrococci of infant skin, Carr and Kloos (1977) reported an increase in the occurrence of micrococci with increasing age up to 10 weeks. Micrococci were rarely isolated from infants less than 1 week of age.

Animal Skin

Micrococci have been isolated from the skin of a variety of mammals, including squirrels of the genus *Sciurus*, rats, raccoons, opossums, horses, swine, cattle, dogs, and various primates (Kloos et al., 1976). The predominant species found on nonhuman mammals studied to date was *M. varians*. *M. luteus* was rarely isolated from nonhuman mammals. Other *Micrococcus* species found on the skin of humans appear to have a narrow host range, as their populations have not yet been discovered on other mammals. Most strains of these specialized species required one or more amino acids and vitamins for growth (Farrior and Kloos, 1975, 1976). The distribution of micrococci on other animals (e.g., birds, reptiles, amphibians, and fish) has not yet been adequately determined.

There are only few data on the distribution of micrococci on fish. Micrococci appear to be numerically diverse on the skin of marine and fresh-water fish, often comprising 1 to 25% of the bacterial population. Similar percentages of micrococci have been found within alimentary tract of different fish (Horsley, 1977). Micrococci predominate in the bacterial population of marine fish captured on the south Australian

coasts, which indicates that this genus is most numerous within these waters (Gillespie and Macrae, 1975). It has been found that micrococci and coryneforms predominate in the bacterial population of sharks (Venkataraman and Sreenivasan, 1953, 1955). The high incidence of micrococci reported on certain fish may be due to their population density in the water or contamination from landing nets or excessive handling by the angler (Horsley, 1977). Micrococci and coryneforms are found among the major groups of bacteria of crustacean shellfish. The percentage composition varies. Williams et al. (1952) found the main groups in the whole Gulf shrimps to be *Acinetobacter* (*Achromobacter*), *Micrococcus*, *Pseudomonas*, and *Bacillus*, whereas Sreenivasan (1959) found that prawns in India carried predominately micrococci and coryneforms. The bacterial flora of the Ontario fresh-water fish examined was similar to that reported from marine fish, in which the species *Pseudomonas* and *Micrococcus* were encountered frequently (Evelyn and McDermott, 1961).

Other Sources

With the exception of animal and dairy products, which may be considered as secondary sources of micrococci, most of the sources, such as soil, estuarine mud, marine and fresh water, plants, fomites, dust, and air, contain small isolated populations of micrococci (Aaronson, 1955; Abd-el-Malek and Gibson, 1948; Baird-Parker, 1962; Doeringer and Dugan, 1973; Kitchell, 1962; Pohja, 1960; Streby-Andrews and Kloos, 1971; ZoBell and Upham, 1944).

Soil is not the primary source of micrococci as had been originally assumed. *Micrococcus luteus* cells died relatively quickly when they were added to natural soil. Microscopic observation showed that the cells were being physically destroyed by bacterial predators in the soil. One of the predators was *Streptoverticillium* sp. (Casida, 1980a, 1980b).

Micrococci formed only a limited part of bacterial population of sea water and therefore they have not been studied thoroughly in marine environments (Anderson, 1962; Brisou, 1955; Wood, 1952; ZoBell and Upham, 1944). It has been found that sand taken from public swimming areas at several North Carolina ocean beaches often contained small populations of *M. luteus*, whereas sand taken from remote ocean island beaches, frequented by small numbers of indigenous animals and a few anglers, only occasionally contained populations of *M. varians* and never *M. luteus*, a species common on human skin, but rare on the skin of other animals.

Some micrococci may well survive in beer. Dickscheit (1961) isolated 33 strains of micro-

cocci from samples of beer and also "yellow sarcinas" which were probably strains of *M. kristinae*, *M. varians*, or *M. luteus*. Also Back (1980) isolated several strains from beer which produced a fruity odor. *M. kristinae* formed sediment in beer bottles and changed the flavor of beer.

Isolation

Direct Isolation from Skin Under Nonselective Conditions

Various semiquantitative procedures have been described for isolating aerobic bacteria from human skin (Kloos and Musselwhite, 1975; Pachtman et al., 1954; Smith, 1970; Williamson, 1965; Williamson and Kligman, 1965). The procedure described by Kloos and Musselwhite (1975) has been used for the isolation of micrococci and is suitable for use with human as well as other mammalian skin.

Isolation of Micrococci from Human and Other Mammalian Skin (Kloos and Musselwhite, 1975)

Sterile cotton swabs were moistened with a detergent containing 0.1% Triton X-100 (Packard) in 0.075M phosphate buffer, pH 7.9 (Williamson, 1965), and rubbed vigorously, with rotation, over approximately 8-cm² sites. Swabbing was performed for 5 s on sites of the forehead, cheek, chin, nares, and axillae that usually contained large populations of bacteria and for 15 s on sites of the arms and legs that usually contained relatively small populations. Swabs taken from the forehead, cheek, chin, external nares, arms, and legs were immediately applied directly on agar media (standard agar plate, 100-mm diameter) by rubbing, with rotation, over the entire surface for two consecutive times. Swabs taken from the anterior nares and axillae were immediately rinsed once in 5 ml of detergent, and the rinse was applied to the surface of agar media. Later, during the course of the study, we observed that adults often contain populations of bacteria on the forehead, cheek, chin, and external nares that were too large to be analyzed by inoculating swabs directly onto media. In these instances, samples taken from a single swab rinse proved to be more satisfactory and produced well isolated colonies.

The Isolating Medium (P agar) of Naylor and Burgi (1956)

Peptone (Difco)	5.0 g
Sodium chloride	5.0 g
Glucose	1.0 g
Agar (Difco)	15.0 g
Distilled water	1 liter

Inoculated agar media are incubated under aerobic conditions at 34°C for 4 days, at which time colonies are counted and recorded according to morphology and pigment. Subcultures (of selected colonies showing *Micrococcus* morphology) are stored at 4°C. For convenience, the original isolation plates could be stored at 4°C for 2 to 3 weeks prior to the isolation of cultures.

This procedure can be modified for use with other mammalian skin as follows.

Isolation of Micrococci from Nonhuman Mammalian Skin (Kloos et al., 1976)

Sites on the body were exposed for swabbing by parting the pelage away from the site area. Swabbing was performed for 5 s on sites in the anterior naris and ventral pouch (opossums only) that usually contained large populations of bacteria and for 15 s on sites of the forehead, forelimbs, hindlimbs, abdomen, and back that usually contained relatively small populations. Swabs taken from the forehead, forelimbs, hindlimbs, abdomen, and back were immediately applied directly on agar media by rubbing, with rotation, over the entire surface for two consecutive times. Swabs taken from the anterior nares and ventral pouch were immediately rinsed once in 5 ml of detergent and then applied to the surface of agar media. (The authors of this chapter have found that rinsing in detergent is also necessary for swabs taken from the face, back, abdomen, and perineum of many Old World monkeys and great apes.)

Direct Isolation from Skin Under Selective Conditions

For shipping agar plates between collecting points or for use with nonhuman mammals, P agar was supplemented with the mold inhibitor cycloheximide (50 µg/ml) (Kloos et al., 1974; Kloos et al., 1976). Many mammals, because of their close contact with soil and foliage, carry large populations of fungi on their skin. If allowed to grow, fungal contaminants may rapidly cover the surface of unsupplemented P agar plates, making the isolation and characterization of bacteria very difficult. If *Bacillus* species are numerous on skin, it may be necessary to supplement P agar with 7% Nace to inhibit their large or spreading colonies. However, such a high amount of sodium chloride will interfere with distinctive *Micrococcus* species colony morphology and *Micrococcus* colonies will not be easily distinguished from *Staphylococcus* colonies.

Selective medium for isolating micrococci (and corynebacteria) in the presence of populations of staphylococci has been described by Curry and Borovian (1976). The nitrofurantoin-containing medium, known as FTO agar, permits the growth of micrococci and prevents the growth of staphylococci. It is particularly useful for sampling areas of the skin such as the nares, axillae, and perineum where *Staphylococcus* populations are usually very large.

FTO Agar Medium for Direct, Selective Isolation of Micrococci from Skin (Curry and Borovian, 1976)

Tryptic soy agar (Difco) or	
Trypticase soy agar (BBL)	40.0 g
Yeast extract	1.0 g
Tween 80	5.0 g
Distilled water	1 liter

After autoclaving and cooling to 48°C, 0.1% of a 0.5 acetone stock of the dye Oil Red O and 10% of a 0.05% acetone stock of nitrofurantoin (Furoxone) are added. To prevent precipitation, the latter is added slowly from a 100-ml graduate into swirling agar. Flasks are then left open or loosely covered in the water bath to allow acetone volatilization prior to pouring and hardening plates on a level surface. The plates can be incubated at 34 to 37°C for 3–4 days for adequate development of *Micrococcus* colonies. To reduce competition and crowding by lipophilic corynebacteria, Tween 80 should be omitted from the formula. FTO agar is conveniently prepared in 700-ml amounts in 1-liter Erlenmeyer flasks.

Cultivation

Most of micrococci grow well on nutrient agar or on P agar (Naylor and Burgi, 1956) at 37°C. The only exceptions are *M. agilis*, which is psychrotrophic and grows best at 22 to 25°C, and *M. halobius*, which requires 5% NaCl in cultivating medium such as nutrient agar or P agar.

Preservation

Cultures of micrococci may be stored on nutrient agar in a refrigerator (5°C) for 3 to 5 months if they are in perfectly sealed tubes. They may also be stored on nutrient agar under liquid paraffin in a refrigerator (5°C) for 1 to 2 years. The most reliable method for long-term preservation is lyophilization, using standard methods (Kirsop and Snell, 1984), or in liquid nitrogen.

Identification

Separation of Staphylococci from Micrococci

The characters that separate staphylococci from micrococci are listed in Table 1. Marked differences in the DNA base and cell wall compositions, fatty acid, and menaquinone patterns permit an accurate separation of the members of the two genera. However, these characters cannot be determined in the routine laboratory; therefore, other characters that can be easily analyzed are also listed in Table 1.

A simple test for the separation of staphylococci from micrococci was described by Schleifer and Kloos (1975). It is based on the ability of staphylococci to produce acid aerobically from glycerol in the presence of 0.4 µg/ml of erythromycin and on their sensitivity to lysostaphin. Recent studies on the isolation of micrococci and staphylococci from dry sausage have indicated that the addition of erythromycin to the glycerol medium is not absolutely necessary (Fischer and

Table 1. Separation of staphylococci from micrococci.

Character	<i>Staphylococcus</i>	<i>Micrococcus</i>	Reference

Teichoic acid	+	-	Schleifer, 1973; Schleifer and Kloos, 1975

S. chromogenes, *S. hyicus*, and *S. intermedius* contain both class I and II FBP-aldolases; *S. caseolyticus* contains only class II. +, positive; ±, weak; -, negative. Symbols in parentheses denote a character frequency of less than 30%.

Schleifer, 1980). Only strains of *Micrococcus kristinae* and a few strains of *M. roseus* produce small amounts of acid aerobically from glycerol, but these organisms can be easily distinguished from staphylococci by their convex colony profile and characteristic colony pigment (Kloos et al., 1974). Furazolidone agar proved to be a suitable medium for the separation of micrococci from staphylococci (Rheinbaben and Hadlok, 1981).

FP Agar for Separating *Micrococcus* from *Staphylococcus* (Rheinbaben and Hadlok, 1981)

Peptone	10.0 g
Yeast extract	5.0 g
NaCl	5.0 g
Glucose	1.0 g
Agar	12.0 g
Distilled water	1 liter

pH 7.0

After autoclaving and cooling to 48°C, 100 ml of a 0.02% acetone solution of furazolidone are mixed under slow stirring with the basal medium. Before pouring the plates, the flasks are left open or loosely covered in a water bath for 3 to min to allow evaporation of acetone.

Micrococci are susceptible to vibriostatic agent 0/129 (0.5 mg/disc) while staphylococci are

resistant to it, which enables one to separate both genera. The recommended medium for 0/129 susceptibility testing is Mueller-Hinton agar (Bouvet et al., 1982).

Differentiation of *Micrococcus* species

Micrococci may be differentiated into nine species by means of tests listed in Table 2. Their pigment production and colony morphology may be used as a simple test for their presumptive identification (Kloos et al., 1974). Certain difficulties may occur in the differentiation of *M. luteus* and *M. lylae*, as both species have several features in common. However, *M. lylae* can be distinguished from *M. luteus* by cream-white or unpigmented colonies, lack of growth on inorganic nitrogen agar, lysozyme resistance, and cell wall peptidoglycan. The most common yellow pigmented species, *M. luteus* and *M. varians*, differ in acid production from glucose, nitrate reduction, lysozyme susceptibility, growth on inorganic nitrogen agar and on Simmons' citrate agar, and oxidase reaction. *M. roseus* differs from other species in having pink colonies, nitrate reduction, and an inability to hydrolyze gelatin.

Table 2. Abbreviated scheme for the differentiation of species of the genus *Micrococcus*.^a

Species	Major pigment ^b	Water-soluble exopigment	Growth on			Nitrate reduction	Oxidase	Aerobic acid from			Lysozyme susceptibility ^c	Arginine dihydrolase	β -Galactosidase	Growth at 37°C	Peptidoglycan type	Amino sugar in cell wall polysaccharide
			Simmons citrate agar	inorganic nitrogen agar	Acetoin			Glucose	Glycerol	Glucose						
<i>M. luteus</i>	Y>CW	-	-	+>±, -	-	->+	+±	-	-	-	S	-	-	+	L-Lys-peptide subunit	Mannosamineuronic acid
<i>M. lylae</i>	CW, U	-	-	-	->±	->+	+±	-	-	-	SR	-	-	+	L-Lys-Asp	Galactosamine
<i>M. varians</i>	Y	-	+>±, -	->±	±, -	+>±	-±	+	-	-	R	-	-	+	L-Lys-L-Ala ₃₋₄	Galactosamine
<i>M. roseus</i>	PR>OR	-	->±	-	+>±	+>±	-±	+±	-	-	SR-R	-	-	+	L-Lys-L-Ala ₃₋₄	Galactosamine
<i>M. agilis</i>	R	-	ND	ND	-	-	+	-	-	-	R	-	+	-	L-Lys-Thr-L-Ala ₃	Glucosamine
<i>M. kristinae</i>	PO	-	-	-	+	->±	+±	++	++	-	R	-	-†	+	L-Lys-L-Ala ₃	Glucosamine
<i>M. nishino miyaensis</i>	O	->+	-	±, -	->±	+±, -	+±	->±	-	-	SR-R	-	-	+	L-Lys-L-Ser ₂ -D-Glu	Galactosamine
<i>M. sedentarius</i>	CW>BY	+±	-	-	-	-	-	->±	-	-	S-SR	+	-	+	Uncertain	-
<i>M. halobius</i>	U	-	ND	ND	-	-	+	+	-	+	R	-	+	+	ND	ND

A single listed symbol denotes a character frequency of about 70–100%; the notation > denotes “a frequency greater than”; a comma between symbols denotes nearly equal frequency. CW, cream-white; U, unpigmented; PR, pastel red; OR, orange red; R, red; PO, pale orange; O, orange; BY, buttermilk yellow; Y, yellow. S, susceptible (minimal inhibitory concentration, MIC: below 5 µg/ml); SR, slightly resistant (MIC: 5–50 µg/ml); R, resistant (MIC: above 100 µg/ml). ++, strong positive; +, positive; ±, weak; -, negative; ND, not determined.

Micrococcus agilis differs significantly from other micrococci in several features. It possesses flagella, is psychrophilic, and exhibits β -galactosidase activity. *M. kristinae* is a clearly separated species, too. It produces acid from glucose under anaerobic conditions. From glycerol aerobically, it forms acetoin and hydrolyses esculin. *M. kristinae* produces unique wrinkled growth on purple agar (Difco) containing 1% maltose. The orange-pigmented *M. nishinomiyaensis* may be further distinguished from *M. kristinae*, which forms very pale orange colonies, by growth on 7.5% NaCl agar, acetoin production, and esculin hydrolysis. *M. sedentarius* differs from other *Micrococcus* species by being resistant to penicillin and methicillin, producing often water-soluble exopigment, growing very slowly, and reacting positively to the arginine dihydrolase test. *M. halobius* can be easily separated from other species, as it requires at least 5% NaCl for growth.

Physiological and Biochemical Properties

Detailed studies on physiological and biochemical properties of micrococci are rather scarce. Most of these studies have been performed before a clear separation of micrococci from staphylococci was possible. Therefore, only those studies will be taken into consideration where a classification as a *Micrococcus* is guaranteed.

Growth Requirements

Chemically defined media for the growth of *M. luteus* and for the growth and the pigmentation of *M. roseus* have been devised (Wolin and Naylor, 1957; Grula et al., 1961; Cooney and Thierry, 1966). Strains of *M. luteus* may grow in a defined medium containing pyruvate or glutamate as carbon and energy source, biotin, and mineral salts (Perry and Evans, 1966; Salton, 1964). Initiation of growth of *M. luteus* in a defined medium depends upon the presence of an iron-binding compound, such as phenolic compounds (e.g., catechol) or ferrichrome (Salton, 1964; Walsh et al., 1971).

Metabolic Properties

Most micrococci are strictly aerobic. Carbon-containing compounds, oxidized to carbon dioxide and water, include acetate, lactate, pyruvate, succinate, fructose, galactose, glucose, glycerol, maltose, and sucrose. Variable oxidation occurs of mannitol, sorbitol, arabinose, rhamnose, ribose, xylose, and starch. Dulcitol is not oxidized (Saz and Krampitz, 1954; Rosypal and

Kocur, 1963; Perry and Evans, 1960, 1966). Glucose is metabolized by fructose-1, 6-biphosphate and hexose monophosphate pathways and citric acid enzymes (Dawes and Holmes, 1958; Perry and Evans, 1966; Blevins et al., 1969). They possess, like most eubacteria, a class II D-fructose-1,6-biphosphate adolase (Götz et al., 1979). However, strains belonging to *M. varians* and *M. kristinae* can also grow facultatively anaerobically and produce L-lactic acid from glucose. An NAD-dependent L-lactate dehydrogenase could be found in representatives of both species (Hartinger and Schleifer, unpublished observations). *M. luteus* possesses an NAD-dependent and an NAD-independent malic dehydrogenase which can oxidize malic acid to oxalacetic acid (Cohn, 1956). A bacterial tyramine oxidase which catalyzes the oxidation of tyramine and dopamine was for the first time isolated from *M. luteus* (*Sarcina lutea*) by Yamada et al. (1967). A phosphoglucomutase, which catalyzes the interconversion of glucose-1-phosphate and glucose-6-phosphate, was purified from *M. luteus* (Hanabusa et al., 1966). The metabolism of exogenous pyrimidine bases and nucleosides was also investigated in *M. luteus* (Auling et al., 1982; Auling and Moss, 1984). The presence of thymidine kinase and phosphorylase could be demonstrated, whereas uridine phosphorylase occurred in a rather weak activity and uridine kinase was not detectable. In contrast to *E. coli*, the pyrimidine nucleotide phosphorylases are not inducible.

Membrane Composition

The cytoplasmic membrane composition, in particular that of *M. luteus*, has been thoroughly studied (Salton, 1987). The major fatty acid component of *Micrococcus* strains is a methyl-branched C₁₅-saturated acid (Girard, 1971; Onishi and Kamekura, 1972; Thirkell and Gray, 1974; Jantzen et al., 1974; Brooks et al., 1980). Micrococci contain relatively high amounts of long-chain aliphatic hydrocarbons in the range of C₂₂ to C₃₃ (Tornabene et al., 1970; Morrison et al., 1971; Kloos et al., 1974). Cardiolipin and phosphatidylglycerol are the major phospholipids. Unidentified phospholipids a and b were described by Komura et al. 1975. *Micrococcus* species partially contain hydrogenated menaquinones of the type MK-7, MK-8, and MK-9 (Jeffries, 1969; Jeffries et al., 1969; Yamada et al., 1967).

All studied micrococci contain cytochromes of *a*-, *b*-, *c*-, and *d*- types (Faller et al., 1980). Besides cytochromes, menaquinones, and carotenoids, NADH, malate, lactate, and succinate dehydrogenases are also part of the electron-transport system of *M. luteus* (Erickson and

Parker, 1969; Crowe and Owen, 1983a). The succinate dehydrogenase was purified and cross reactions with specific antisera directed to the membrane-bound enzyme of other micrococci could be shown, but no cross reaction occurred with the enzyme from a wide variety of Gram-positive and Gram-negative bacteria (Crowe and Owen, 1983b). The proton-translocating ATP synthase of *M. luteus* has been thoroughly studied (Salton and Schor, 1974; Schmitt et al., 1978).

It consists of the typical F_0F_1 complex. The cytoplasmic membrane is also the site of enzymes involved in phospholipid, peptidoglycan, and teichuronic biosynthesis (De Siervo and Salton, 1971; Park and Matsushashi, 1984; Traxler et al., 1982). Membranes of *M. luteus* are unusually rich in mannose; much of this is bound in succinylated lipomannan (Owen and Salton, 1975). Part of the mannose is also found in membrane glycoproteins (Doherty et al., 1982). The occurrence of glycoproteins is a rather unusual feature for eubacteria.

Genetics Properties

DNA Relationships

Transformation studies by Kloos (1969a) and DNA-DNA hybridization studies by Ogasawara-Fujita and Sakaguchi (1976) showed that there is no close genetic or DNA relationship among members of the species *M. luteus*, *M. roseus*, and *M. varians*. Schleifer et al. (1979) demonstrated that DNA homology values between the type strains of *M. luteus* and *M. lylae* were in the range of 40 to 50% at optimal reassociation conditions, whereas values of only 10 to 18% were obtained between these species and *M. kristinae* or *M. varians*. Kloos et al. (1974) showed a significant genetic relationship between *M. luteus* and *M. lylae* in transformation studies. Genetics exchange occurred at about 1 to 5% of homologous values using DNA isolated from *M. lylae* with *M. luteus* auxotrophic recipients. An epigenetic relationship between *M. luteus* and *M. lylae* has been demonstrated by comparative immunological studies of catalase using both double-immunodiffusion tests and quantitative micro-complement fixation assays (Rupprecht and Schleifer, 1977). The nucleotide sequence of a 23S rRNA gene of *M. luteus* was determined (Regensburger et al., 1988a). From sequence comparison to 23S rRNA genes from other bacteria, specific probes could be constructed (Regensburger et al., 1988b). One probe (pAR28) reacted only with *M. luteus* and *M. lylae*, while another probe (pAR27) reacted with all micrococci and arthrobacters.

Transformation

Genetic exchange in the genus *Micrococcus* was first demonstrated by transformation of Fleming's *M. luteus* strain (formerly *M. lysodeikticus*) (Kloos, 1968; Kloos and Schultes, 1969; Mahler and Grossmann, 1968; Okubo and Nakayama, 1968). Following the determination of optimal conditions for transformation (Kloos, 1969b), a procedure for transformation was developed for use in genetic mapping (Kloos and Rose, 1970). Transformation has not been reported in other micrococcal species.

Transformation of *Micrococcus luteus* ATCC 27141 Auxotrophs (Kloos and Rose, 1970)

An 18-h P agar slant culture of the recipient strain was suspended in 1 ml saline and diluted 1/100 in saline. Aliquots of 0.1 ml [about 5×10^6 colony-forming units (CFU)] from the diluted suspension were added to duplicate tubes containing 1 ml defined broth supplemented with 20 $\mu\text{g/ml}$ of the required metabolite (e.g., L-tryptophan, L-histidine, adenosine, etc.) (Kloos, 1969b). Cultures were shaken in a 34°C water bath with a Burrell Wrist-Action Shaker at a setting of 4 for 24 h. Following growth, cells (about $1-3 \times 10^8$ CFU/ml) were centrifuged and resuspended in 1 ml transformation buffer: 50 mM Tris (hydroxymethyl) aminomethane + 1-mM SrCl_2 , pH 7.0. Donor DNA, 0.1 μg in crosses or 10 μg for the construction of double auxotrophic mutants for three-point crosses, in 0.1 ml saline was added to each tube and the mixtures were shaken in a 30°C water bath at a setting of 4 for 30 min. DNA uptake was terminated by the addition of deoxyribonuclease (5 $\mu\text{g/ml}$) and 5 mM MgSO_4 with incubation at 37°C for 15 min. After treatment, cells were centrifuged and resuspended in 1 ml saline. Aliquots of 0.1 ml were taken from an appropriate saline dilution of the original suspension and spread on duplicate defined agar plates. Prototrophs were scored after incubation at 34°C for 72 h. Donor-type cotransformants (on appropriate supplemented defined agar plates) were scored after incubation for 96 h. Using the above procedure, transformation frequencies of 0.1–0.7 percent of recipient CFU could be obtained with prototroph donor DNA.

Competence in transformation has been demonstrated in *M. luteus* strains ATCC 27141 and its relatives (ATCC 15801, PU, UM, WRU) and strains ATCC 540 and ATCC 8673.

Chromosomal Gene Arrangements

Tryptophan and histidine biosynthesis genes have been mapped in *M. luteus* by using two-point "best-fit" and donor-types (contransformation) analyses and three-point transformation (Kane-Falce and Kloos, 1975; Kloos and Rose, 1970). These studies have indicated that at least two histidine genes are closely linked, probably contiguous, to the tryptophan gene cluster containing *trpE*, *trpC*, *trpB*, and *trpA* genes, in that order. Tryptophan genes are located in the main cluster mentioned above and at least in one other

unlinked site containing *trpD* and *trpF*. Histidine genes are distributed in at least four regions of the chromosome. The largest cluster contains four genes: *his* (EAH or F), *hisB*, *hisC*, and *his* (EAH or F). Mapping purine biosynthesis genes by the two-point best-fit method has indicated significant separation of the purine genes *purE*, *purJ*, and *purC* and no linkage of these genes to *purH* (Mohapatra and Kloos, 1974, 1975).

Plasmid Composition

Plasmids have been detected in a small to moderate percentage (7–55%) of strains in most species of micrococci (Mathis and Kloos, 1984). They have not yet been reported in the species *M. lylae* and *M. sedentarius*. Most strains carrying plasmids exhibit only one or two types, ranging in size from 1 to 100SMDa. Plasmid patterns appear to be slightly more complex in *M. nishinomiyaensis*. Thirty-six percent of strains in this species carried two to three different plasmids. To date, most micrococcal plasmids remain cryptic. Several small plasmids identified in *M. nishinomiyaensis*, *M. roseus*, *M. varians*, and *M. luteus* have been studied with restriction endonucleases and may be suitable for use as cloning vectors following some modification.

Pathogenicity for Humans

The data about possible pathogenicity of micrococci for humans are very poor and controversial. Micrococci, however, may be considered as opportunistic pathogens, particularly in view of the increasing number of immunocompromised patients. Micrococci have been reported to be associated with various infections, especially those of the urinary tract (Meers, et al., 1975; Roberts, 1967; Sellin et al., 1975; Telander and Wallmark, 1975). However, these and similar reports cannot be evaluated because the discussed strains were either not sufficiently taxonomically described or incorrectly identified. As a result of the present classification, all the strains from such infections tested to date have been shown to be staphylococci.

Therefore, only the papers of the last 10 to 15 years describing human infections caused by micrococci can be taken into consideration. A case of septic shock caused by *Micrococcus luteus* was described by Albertson et al. (1978). *M. luteus* was reported in a case of cavitating pneumonia of an immunosuppressed patient (Souhami et al., 1979) and in a case of meningitis (Fosse et al., 1986). *M. kristinae* has been isolated in pure culture from several types of infections in the U.S.A. *M. sedentarius* has been found to be associated with pitted keratolysis

(Nordstrom et al., 1987). Micrococci have been isolated from blood and surgical specimens of patients associated with heart diseases and septic complications following cardiac surgery. Some of the isolates were probably *M. lylae* strains. There is no clear proof that micrococci are pathogenic for nonimmunocompromised humans. Pathogenicity of micrococci for plants has not yet been described.

Application

Micrococci have been reported to be used in the processing of fermented meat products to improve their color, aroma, flavor, and keeping quality (Kitchell, 1962; Niinivaara and Pohja, 1957; Pohja, 1960). However, based on an updated classification of these organisms, most strains used in processing have proved to be staphylococci, in particular, *S. carnosus*, and occasionally *S. xylosus* (W.E. Kloos, unpublished observations). The true micrococci that have been useful in meat processing have proved to be *Micrococcus varians*. Studies by Fischer and Schleifer (1980) showed that besides *M. varians*, *M. kristinae* could also be isolated from fermented sausage. Species such as *Micrococcus luteus* and *M. varians* have been widely used in industries as assay organisms to test various antibiotics in body fluids, feeds, milk, and pharmaceutical preparations (Bowman, 1957; Coates and Argoudelis, 1971; Grove and Randall, 1955; Kirshbaum and Arret, 1959; Simon and Yin, 1970); the vitamin biotin (Aaronson, 1955); and the enzyme lysozyme (Dickman and Proctor, 1952).

Micrococci are among the few bacteria that synthesize long-chain (C_{21} – C_{34}) aliphatic hydrocarbons. These hydrocarbons may have potential economic value if they can be produced and extracted economically and then processed into useful lubricating oils or other petroleum substitutes (Kloos et al., 1974; Morrison et al. 1971; Tornabene et al., 1970).

Renibacterium

HANS-JÜRGEN BUSSE

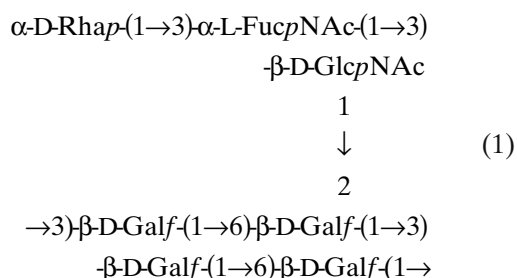

Renibacterium salmoninarum is the causative agent of Bacterial Kidney Disease (BKD), a chronic and systemic infection of salmonid fish such as Pacific and Atlantic salmon, grayling (*Thymallus thymallus*), lake trout (*Salvelinus namaycush*), and several other species of trout and char. However, *R. salmoninarum* has also been isolated from several non-salmonid fish species that did not show any signs of the disease (Traxler and Bell, 1988). It is one of the most serious diseases in salmonid farming in the Atlantic and Pacific region (Margolis and Evelyn, 1987; Fryer and Lannan, 1993; Olea et al., 1993). The disease occurs mainly in freshwater, but significant mortality also occurs in saltwater (Banner et al., 1983).

The systemic disease, which is a slowly developing chronic infection, derives its name from off-white bacterial lesions in the kidney. BKD is histopathologically characterized as a systemic diffuse granulomatous inflammation. In later stages many organs may become affected and the body cavity may become filled with fluid. Severely infected fish may show no obvious clinical symptoms or pale gills (indicative of anemia), exophthalmia, abdominal distension, skin blisters filled with clear or turbid fluid, shallow ulcers, hemorrhages and, infrequently, intramuscular cavities (Wood and Yasutake, 1956; Fryer and Sanders, 1981; Bruno, 1986). The bacterium is transmitted horizontally, probably by a fecal-oral route (Balfry et al., 1996), and vertically in the egg (Evelyn et al., 1984; Lee and Gordon, 1987). *Renibacterium salmoninarum* occurs extracellularly and intracellularly (Bell, 1961) and survives and multiplies inside fish macrophages (Young and Chapman, 1978).

Therapeutic treatment of diseased fish with antibiotics such as clindamycin, erythromycin, kitasamycin, penicillin G and spiramycin is only of limited use but effective prophylactically (Austin, 1985).

The genus *Renibacterium* with the single species *Renibacterium salmoninarum* was originally described by Sanders and Fryer (1980) and later the description was emended by Goodfellow et al. (1985). Phylogenetically, *Renibacterium salmoninarum* is next but only moderately related to the genera *Arthrobacter* and *Micrococcus* (Stackebrandt et al., 1988; Grayson et al., 2000a).

Cells of this species are fastidious, slowly growing short rods often occurring in pairs that stain strongly Gram positive. For cultivation, KDM-2 medium is recommended (DSMZ, 2001) and the presence of L-cysteine has been demonstrated to support growth (Daly and Stevenson, 1993). Optimal growth occurs between 15°C and 18°C. All strains studied by Goodfellow et al. (1985) are positive for catalase, phosphatase, acid phosphatase, esterase (C8), α -glucosidase, trypsinase, and degradation of casein, tributyrin and Tween 20, and they are sensitive to carbenicillin and cephaloridine treatment. The quinone system consists mainly of menaquinone MK-9 and minor amounts of MK-10. Present in the complex polar lipid profile is diphosphatidyl glycerol, two major and six or seven uncharacterized glycolipids, and two unknown minor phospholipids. In the fatty acid profile, the major components are C_{15:0} anteiso, C_{15:0} iso and C_{17:0} anteiso (Embley et al., 1983). Major cell wall sugar is glucose; arabinose, mannose and rhamnose are also present. The peptidoglycan type is A3 α consisting of alanine, glutamic acid, glycine and the diamino acid lysine (Kusser and Fiedler, 1983). Electron microscopic studies have demonstrated the presence of a capsule in the outer layer (Dubreuil et al., 1990). The galactose-rich polysaccharide (GPS) consists of a heptasaccharide repeating unit composed of D-galactose, D-rhamnose, N-acetyl-D-glucosamine and N-acetyl-L-fucosamine in a molecular ratio of 5.4 : 1.1 : 1.4 : 1.1 (Sum et al., 1998; Eq. 1). GPS was found to constitute 60–70% of the dry weight of the protein-free cell wall preparations (Fiedler and Draxl, 1986). The G+C content of genomic DNA is 55.5 mol% (Banner et al., 1991). The structure of the heptasaccharide repeating unit (Sum et al., 1998) is

The cell surface has been shown to be hydrophobic and to have hemagglutinating properties associated with immunomodulation and virulence (Daly and Stevenson, 1987; Bruno, 1988; Wood and Kaattari, 1996). The hemagglutinin was demonstrated to be identical with the soluble heat stable virulence factor p57 (Daly and Stevenson, 1990). The 57-kDa protein, which also is designated “major soluble antigen (MSA), is predominantly localized on the bacterial cell surface, with significant levels released to the environment. Two copies of the MSA encoding gene (*msa1* and *msa2*) are found in *R. salmoninarum* and both genes are expressed under in vitro conditions (O’Farrell and Strom, 1999; Rhodes et al., 2002). Another antigenic group has been identified which is characterized by a major 30-kDa protein (Bandín et al., 1992).

MSA is the target antigen in several immunological diagnostic assays and PCR-based methods have been developed to detect specific fragments of the MSA encoding gene or the corresponding mRNA (McIntosh et al., 1996; Chase and Pascho, 1998; Cook and Lynch, 1999). Another PCR-approach has been developed to specifically detect *R. salmoninarum* using reverse transcription and nested PCR amplification of hypervariable regions within the 16S rRNA sequence (Magnusson et al., 1994).

The genome of *R. salmoninarum* has been demonstrated to harbor two rRNA operons, which are designated “*rrnA*” and “*rrnB*” (Grayson et al., 2000a). The intergenic spacer between 16S-23S rRNA coding genes (ITS1) was found to consist of 534 bp and to be highly conserved, showing not more than 4 bp difference among different isolates (Grayson et al., 1999; Grayson et al., 2000b). The length of the 23S-5S rRNA intergenic spacer is conserved as well, consisting of 219 bp, and only a small variation exists in isolates derived from areas of the world relatively isolated from the mainstream intensive salmonid cultivation (Grayson et al., 2000a).

KDM-2 Medium (DSMZ-Medium 435; DSMZ, 2001)

Peptone	10.0 g
Yeast extract	0.5 g
L-Cysteine · HCl × H ₂ O	
have a look in the	
Online catalogue of	
strains from DSMZ!	1.0 g
Calf serum	100.0 ml
Distilled water	900.0 ml
Adjust pH to 6.5.

The Genus *Stomatococcus*: *Rothia mucilaginosa*, basonym *Stomatococcus mucilaginosus*

ERKO STACKEBRANDT

The species *Stomatococcus mucilaginosus* (Bergan and Kocur, 1982) was recently assigned to the genus *Rothia* as *Rothia mucilaginosa* (Collins et al., 2000). A literature search in Medline indicated that the name change to *Rothia mucilaginosa* has been used in only a single publication (Kazor et al., 2003); as the majority of mostly clinical reports still refer to the basonym *Stomatococcus mucilaginosus*, this name will be used until the revised classification has been fully adopted by medical microbiologists. Electronic publication will facilitate fast updates of taxonomic rearrangements and subsequent changes.

The rationale for the reclassification of *Stomatococcus mucilaginosus* was based mainly on the topology of the 16S rRNA gene tree and some common phenotypic differences between members of *Rothia* and *S. mucilaginosus*. As a consequence of the classification of a mouse isolate as *Rothia nasimurium* type strain CCUG 35957^T (Collins et al., 2000), *Stomatococcus mucilaginosus* branched equidistantly between *R. dentocariosa* and *R. nasimurium* and was therefore reclassified as a member of *Rothia*. Recently, *Rothia amarae* JCM 11375^T was described (Fan et al., 2002), showing a remote relatedness to type strains of the other *Rothia* species. Though formally correct, the authors (Collins et al., 2000; Fan et al., 2002) failed to provide clear-cut evidence that the reclassification of *Stomatococcus* and the affiliation of strains JCM 11375^T and CCUG 35957^T are justified. The past years have shown the high correlation between phylogenetic clustering and distribution of chemotaxonomic properties, and the delineation of groups of actinobacteria at the generic level was often based on their chemotaxonomic coherency. Studies leading to the description and reclassification of the new *Rothia* species have provided information that is either lacking or only fragmentary. If available, these characters are often not as coherent as expected for members of the same genus. The need for a comparative study on chemotaxonomic and phenotypic

properties, including all type strains, is therefore obvious.

Taxonomy

The genus *Stomatococcus*, with *S. mucilaginosus* as its only species, was first described after significant phylogenetic and biochemical differences to otherwise morphologically similar organisms were detected (Bergan and Kocur, 1982). *Stomatococcus mucilaginosus* (“*Staphylococcus salivarius*,” Andrewes and Gordon, 1907, or “*Micrococcus mucilaginosus*” Bergan et al., 1970) is defined to contain organisms which are Gram-positive, nonmotile, nonsporeforming, encapsulated, spherical cells and which show either a weakly positive or a negative catalase reaction. Cells are arranged mostly in clusters, and occasionally in pairs or tetrads. Originally, following the tradition of defining higher taxa by morphology, *Stomatococcus*—together with the genera *Micrococcus*, *Staphylococcus* and *Planococcus*—was described to constitute the family Micrococcaceae (Bergan and Kocur, 1982; Schleifer, 1986), although a dissection of this family on phylogenetic grounds had already been proposed by Stackebrandt and Woese (1979). Chemical and phylogenetic evidence showed the species *S. mucilaginosus* is constituted by one line of descent within the order Actinomycetales and thus the genus was included in the emended family Micrococcaceae (Stackebrandt et al., 1997), which also included *Micrococcus*, *Arthrobacter*, *Renibacterium*, *Rothia*, *Kocuria* and *Nesterenkonia*. *Rothia dentocariosa* and *Stomatococcus mucilaginosus* were branching adjacent to each other, having a 16S rRNA gene sequence similarity of 97.7%. *Rothia nasimurium* and *R. amarae* are slightly less closely related to these two species and among themselves have a 95.5–96.8% similarity. Members of *Kocuria* are the phylogenetically nearest neighbors (Fig. 1). All members of *Rothia* and *Stomatococcus* possess the family Micrococcaceae-specific 16S

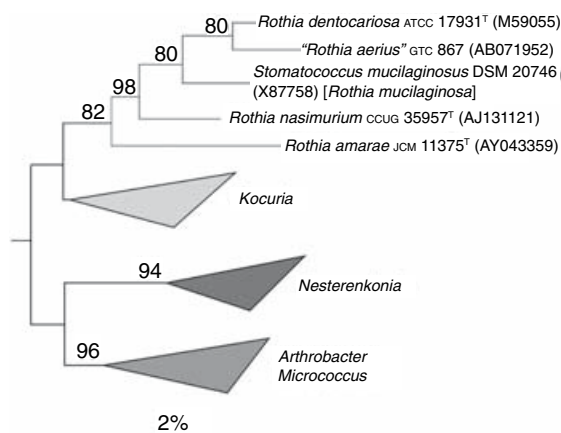

Fig. 1. Phylogenetic tree generated on the basis of almost complete 16S rRNA gene sequences, showing the relationship of *Stomatococcus mucilaginosus* [*Rothia mucilaginosus*] to members of the genus *Rothia* and related genera. The tree was generated by the additive treeing algorithm of De Soete (1983) using the Jukes and Cantor (1969) correction. Bootstrap value was calculated for 500 replicate trees. The bar corresponds to a 2% difference in nucleotide sequences.

rRNA gene signature nucleotides (Stackebrandt et al., 1997). Analysis of the aligned sequences for the presence of species-specific signature nucleotides (Table 1) confirms the phylogenetic branching as shown in Fig. 1, i.e., the isolated position of *S. nasimurium* and *S. amarae* as well as the clustering of *Rothia dentocariosa*, *S. mucilaginosus*, and the as yet undescribed species "*Rothia aerius*" (Y. Kawamura and T. Ezaki, unpublished observation).

The phenotype of members of *Stomatococcus* and *Rothia* is similar and hardly discriminatory enough to differentiate between species. All members are positive, or at least some strains of a species are positive, for the following characteristics: facultatively anaerobic, nonmotile, acid

production from glucose and trehalose, esculin hydrolysis, and nitrate reduction. All members are negative for the following characteristics: acid production from mannitol and production of sorbitol, urease, and alkaline phosphatase. Other reactions, most of which have not been determined for *R. nasimurium*, are indicated in Table 2. Additional tests for *S. mucilaginosus* and *Rothia* spp. (Gerencser and Bowden, 1986; Collins et al., 2000; Fan et al., 2002) are given in their species description.

Stomatococcus mucilaginosus strains differ from members of *Micrococcus* and catalase-positive staphylococci by failure to grow on media containing 5% NaCl (Bergan and Kocur, 1982; McWhinney et al., 1992; Guermazi et al., 1995). Strains of *Rothia dentocariosa* differ in their ability to grow in 4% NaCl, and none grows in 6% NaCl.

Various commercial systems have been applied to identify and characterize *S. mucilaginosus* strains, including the Biolog identification system (Biolog, Inc., Hayward, CA; Miller et al., 1993), Staph-ident system (bioMérieux Vitek, Hazelwood, MO; Rhoden and Miller, 1995) and API 50 CH system (bioMérieux, Marcy l'Etoile, France; van Tiel, 1995). When compared to conventional identification, the accuracy of the Staph-ident system was 35.3% only, and 41% of strains required an additional test for identification.

Habitats

Stomatococci are normal inhabitants of the mouth and the upper respiratory tract of humans (Bergan et al., 1970), comprising about 3.5% of the predominant cultivable aerobic microflora of the human oral cavity. *Stomatococcus mucilaginosus* is indigenous to the human tongue and

pharynx, but it has also been isolated from the nasopharynx, bronchial secretions, and blood (Gordon, 1967; Bergan et al., 1970, Rubin et al., 1978; Pinsky et al., 1989) and from smears of human dental plaque (Bowden, 1969). It may also be among the early colonizers of human teeth (Nyvad and Kilian, 1987). The microbial population has been studied by a culture-independent approach (Kazor et al., 2003) and *S. mucilaginosus* was found among those species most associated with healthy subjects.

Before 1990, it was generally believed that *S. mucilaginosus* was an unlikely pathogen because of its presence as a member of the indigenous microflora of the upper respiratory tract in humans. However, the increasing number of reports on the presence of *S. mucilaginosus* in clinical cases could not be ignored. From 1990 on, the literature treats *S. mucilaginosus* as an opportunistic pathogen (Ascher et al., 1991a; Ascher et al., 1991b). McWhinney et al. (1992) even considered this organism as an important pathogen in severely immunocompromised pediatric patients. Clinicians and microbiologists were asked to be increasingly aware of this pathogen (Kaufhold et al., 1992).

Stomatococcus mucilaginosus has been isolated from patients with severe pericoronitis of mandibular third molars and was found in 71% of patient samples (Peltroche-Llacsahuanga et al., 2000). When caries-reducing sucrose substitutes, e.g., palatinose or leucrose, were metabolized in a batch fermenter, *S. mucilaginosus* fermented these substitutes to produce a water-

insoluble polysaccharide. This polysaccharide may be cleaved by the autochthonous flora to produce cariogenic products (glucose and fructose) that another population of the dental flora can use to produce acids (Peltroche-Llacsahuanga et al., 1991).

Stomatococcus mucilaginosus has also been reported in populations of the conjunctival flora of rabbits (8% of specimens; Cooper et al., 2001) and in sickly six-week-old broiler chickens (4% of specimens; Awan and Matsumoto, 1998).

Swab samples from the human tongue or other parts of the oral cavity are inoculated onto blood agar or trypticase soy agar and incubated at 30–37°C. Colonies are usually mucoid, transparent, or whitish and adherent to the agar surface.

Media and Cultivation

Under aerobic conditions, stomatococci show good growth within 24–30 h at 30°C on complex media such as brain heart infusion agar (Difco 0418) or casein peptone (tryptic digest)-glucose-yeast extract-NaCl (1:0.5:0.5:0.5%, w/v) broth, pH 7.2–7.4. No growth occurs in media prepared with 5% NaCl or 40% bile (Baird-Parker, 1974).

Preservation

Stock cultures are routinely maintained on agar slants using one of the media indicated above

and stored at 4°C. Cultures are transferred to fresh medium every 4 weeks. Liquid cultures can be frozen at -12°C and survive several months. Long-term preservation is done by lyophilization or storage in liquid nitrogen. No information on the viability has been reported.

Identification

The morphological and biochemical tests used for staphylococci and micrococci are recommended (Bergan and Kocur, 1986). Cells are nonmotile and spherical, arranged mostly in clusters, occasionally in pairs or tetrads. A copious capsule is formed (Silva et al., 1977). Oxidase and benzidine tests are negative (Schleifer, 1986). The catalase reaction is negative in about one-half of the strains investigated (Gordon, 1967; Bergan and Kocur, 1986). Cells are resistant to lysostaphin (Schleifer and Kloos, 1975). A variety of sugars is fermented anaerobically. Acid but no gas is produced, although no information on end products is available. *Stomatococcus mucilaginosus* can easily be differentiated from other Gram-positive bacteria when a combination of commercially available identification systems and conventional biochemical tests is combined with adherence to agar surfaces, poor growth on Mueller-Hinton agar, and the presence of a capsule (Kaufhold et al., 1992).

Stomatococcus mucilaginosus is susceptible to micrococcal bacteriophages, most of which are also specifically active on *Micrococcus luteus* (Bauske et al., 1978). *Stomatococcus*-specific phages have as yet not been found. Cytochrome patterns (Stackebrandt et al., 1983) and fatty-acid and polar lipid patterns (Jantzen et al., 1974; Amadi et al., 1988) distinguish stomatococci from micrococci and staphylococci (Lennarz and Talamo, 1966; Faller et al., 1980; Nahaie et al., 1984) but not clearly from other members of *Rothia* (see Table 3). With respect to the presence of unsaturated menaquinones, *S. mucilaginosus* resembles staphylococci and *M. luteus*, but not the other *Micrococcus* species (Amadi et al., 1988); information on the menaquinone composition of *Rothia* species lacks coherency (Table 3). The peptidoglycan type differs among strains of *S. mucilaginosus*, in that the interpeptide bridge consists of L-alanine, D-serine, or glycine (Schleifer and Kandler, 1972; Stackebrandt et al., 1983; Table 3). This type is also found in other members of Micrococcineae, i.e., *Rothia*, *Arthrobacter*, *Kocuria* and *Renibacterium* (see the chapter Introduction to the Taxonomy of Actinobacteria in this Volume). The G+C content of DNA is slightly higher in *S. mucilaginosus* than that of *Rothia* species (Table 3). Despite the variation in peptidoglycan types and the G+C con-

tent of 56–60.5 mol%, all 10 strains of *S. mucilaginosus* included in DNA hybridization studies revealed such a high degree of relatedness (more than 75%) that their allocation to a single species seems justified. The 16S rRNA gene sequence of the type strain contains some *Stomatococcus mucilaginosus*-specific nucleotides (16S rRNA gene positions 139-224: U-A; 453-479: A-U; 467: G; 631: A; 591-648: U-A; 678-713: U-A; 1009-1020: A-U), so that new isolates can be allocated unambiguously to this species. Restriction fragment length polymorphism has been applied to isolates from neutropenic patients with hematological malignancies. These strains were found to be of diverse genetic origin (Granlund et al., 1996).

The type strain of *Stomatococcus mucilaginosus* [*Rothia mucilaginosus*] is CCM 2417^T (=DSM 20746^T = ATCC 25256^T = NCTC 10663^T).

Pathogenicity

Strains of *S. mucilaginosus* have been isolated from the blood cultures of patients with endocarditis, in patients who were intravenous drug abusers (Coudron et al., 1987; Relman et al., 1987), and in patients with pre-existing valvular heart disease (Rubin et al., 1978; Prag et al., 1985), bacteremia (Barlow et al., 1986), and recurrent peritonitis during chronic ambulatory peritoneal dialysis (Ragnaud et al., 1981). Both immunocompetent and immunosuppressed patients are affected. From 1990 on, the number of cases increased in which the organism was isolated from blood, the oral region, and wound sources causing bacteremia and septicemia that, among other factors, developed after endocarditis, surgery, bone marrow transplantation (Cobo et al., 1998), and from infected devices such as indwelling vascular catheters (Mitchell et al., 1990; Ascher et al., 1991a; Kaufhold et al., 1992). More alarming was the finding that *S. mucilaginosus* was also recovered from lower tract infection in a patient with AIDS (Cunniffe et al., 1994), patients with meningitis (Ben Salah et al., 1994; Guermazi et al., 1995; Abraham et al., 1997; Park et al., 1997; Skogen et al., 2001), acute leukemia (Mustafa et al., 1993; Granlund et al., 1996; Trevino et al. 1998; Paci et al., 2000), neutropenia (Oppenheim et al., 1989; Henwick et al., 1993; Gruson et al., 1998), osteomyelitis (Nielsen, 1994), choroid plexus infection (Guermazi et al., 1995), postoperative spondylodiscitis (Bureau-Chalot et al., 2003), and central nervous system infections (Goldman et al., 1998).

All but one isolate from neutropenic patients were sensitive to benzylpenicillin and all were sensitive to vancomycin (McWhinney et al., 1992). In another study, the minimal inhibitory

Abbreviations: MK, menaquinone, MK-6, -7, -8 and -9, menaquinones with 6–9 isoprene side chains, respectively, MK-6(H₂), -7(H₂), and -8(H₂), the same as MK-6, -7 and -8 (but have two hydrogens added to the side chain double bonds); DPG, diphosphatidylglycerol; PG, phosphatidylglycerol; PI, phosphatidylinositol; PL, unidentified phospholipid; GL, unidentified glycolipid, and n.d. not determined.

^aThe peptidoglycan type is indicated as L-Lys-L-Ser-L-Ala by Schleifer and Kandler (1977).

^bUnpublished data, kindly provided by Peter Schumann.

^cFan et al. (2002) report the peptidoglycan type L-Lys-Glu-Ala in the species description, but the presence of lysine and alanine in the text. The code A3a refers to the later type.

From Gerencser and Bowden (1986), Collins et al. (2000), Fan et al. (2002) and the chapter Introduction to the Taxonomy of Actinobacteria.

concentration (MIC) at which 55% and 90% of *S. mucilagenosus* isolates from healthy and neutropenic skin and gingiva were respectively inhibited was determined for a broad range of antibiotics (von Eiff et al., 1995). Rifampicin was the most active compound, but ampicillin, imipenem, cefotaxime and clarithromycin were similarly effective. Aminoglycosides were less effective than β -lactam antibiotics, and only streptomycin could be applied successfully in the study of Chomar et al. (1991). Cuniffe et al. (1994) reported that an *S. mucilagenosus* isolate was sensitive to rifampicin but resistant to penicillin, co-trimoxazole and ciprofloxacin. Strains isolated from neutropenic patients who had received ciprofloxacin as part of their prophylactic regime were more resistant to this antibiotic than strains isolated from non-neutropenic patients who had not received the antibiotic (van Tiel et al., 1995). A similar effect was reported by Granlund et al. (1996). Bureau-Chalot et al. (2003) treated *S. mucilagenosus*-caused spondylodiscitis by intravenous treatment with cefotaxime and fosfomycin, followed by oral doses of rifampicin and pristinamycin. Abraham et al. (1997) successfully treated meningitis with a combination of intravenous penicillin G and chloramphenicol and intrathecal vancomycin. Vancomycin was also effective in the study of Granlund et al. (1996). Apparently, different isolates identified as being members of *S. mucilagenosus* react differently to different doses and antibiotics, but *S. mucilagenosus* bacteremia is readily treatable with antibiotics (Ascher et al., 1991a; Ascher et al., 1991b).

The Family Cellulomonadaceae

ERKO STACHEBRANDT, PETER SCHUMANN AND HELMUT PRAUSER

Introduction

The short history of the family Cellulomonadaceae, suborder Micrococccineae, order Actinomycetales, class Actinobacteria, reflects the changes in the interpretation of sequence based phylogenetic data. When defined originally (Stackebrandt and Prauser, 1991), the family Cellulomonadaceae included the genera *Cellulomonas* (Bergey et al., 1923; emend. Clark, 1952; emend. Stackebrandt et al., 1982), *Oerskovia* (Prauser et al., 1970; emend. Lechevalier, 1972), *Promicromonospora* (Krassilnikov, 1961), and *Jonesia* (Rocourt et al., 1987). The rationale for the establishment of this family was based mainly on comparative analysis of 16S rRNA cataloguing data of the type species of some genera of the order Actinomycetales (Stackebrandt et al., 1980d; Stackebrandt et al., 1983). Phylogenetically, neighboring taxa to Cellulomonadaceae were *Promicromonospora*, *Cellulosimicrobium*, *Rarobacter* (Fig. 1), as well as *Arthrobacter*, *Renibacterium*, *Micrococcus*, *Stomatococcus*, *Dermatophilus* and *Microbacterium* and some other related genera (not shown). Members of the Cellulomonadaceae were phenotypically characterized by a combination of phenotypic characters that distinguish them from the adjacent taxa: 1) from *Microbacterium* and related taxa, by the type A crosslinking of the peptidoglycan moieties; 2) from *Dermatophilus* and *Brevibacterium*, by the lack of meso-diaminopimelic acid in the peptidoglycan; and 3) from all other members of the order, by the presence of a specific phospholipid type.

The decision to exclude the genus *Jonesia* from the family (Rainey et al., 1995) was due to the change in methodology, i.e., the replacement of 16S rRNA cataloguing by reverse transcriptase sequencing of 16S rRNA and shortly thereafter by analysis of polymerase chain reaction (PCR)-generated 16S rDNA. As a consequence of phylogenetic branching, the order changed and the phylogenetic distinctness of *Jonesia denitrificans* became apparent. *Promicromonospora* was excluded from the family on similar grounds and now constitutes the monogeneric family

Promicromonosporaceae (Stackebrandt et al., 1997).

The emended family Cellulomonadaceae, as described by Stackebrandt et al. (1997) on the basis of phylogenetic position and the distribution of signature nucleotides of the 16S rRNA gene of all validly described actinomycete genera, is a member of the suborder Micrococccineae, order Actinomycetales (Stackebrandt et al., 1997). The family then contained the genera *Cellulomonas* and, tentatively, *Rarobacterfaecitabidus*. Shortly afterwards, several new genera were described as new members of the Micrococccineae (Groth et al., 1997a; Groth et al., 1997b; Martin et al., 1997; Groth et al., 1999a, b) and the addition of new 16S rDNA sequences to the database of actinomycete species changed the phylogenetic position of a few taxa and stabilized other taxa. The phylogenetic dendrogram clearly disconnected *Rarobacterfaecitabidus* phylogenetically from the family Cellulomonadaceae. New families were described, i.e., Rarobacteraceae, Bogoriellaceae, Dermacoccaceae, and Sanguibacteraceae (Stackebrandt and Schumann, 2000), leaving Cellulomonadaceae as a family with two genera: *Cellulomonas* and *Oerskovia*.

At present, the family comprises the genera *Cellulomonas* and *Oerskovia* (Stackebrandt et al., 2002), embracing 10 and 4 species, respectively, the type strains of which are listed in Table 1, together with the accession numbers of their 16S rDNAs. Both genera were united under *Cellulomonas* (Stackebrandt et al., 1982) when phylogenetic relatedness based upon 16S rDNA catalogues (Stackebrandt et al., 1980c) was considered more significant than differences in chemotaxonomic properties, such as the amino acid composition of peptidoglycan. In the years following the unification, the high correlation between phylogenetic clustering and chemotaxonomic distinctness became apparent (see chapter "Introduction to the Taxonomy of Actinobacteria") and the reevaluation of phenotypic properties of members of these two genera led to taxonomic consequences: firstly, *Cellulomonascellulans* was excluded from *Cellu-*

lomonas and reclassified as *Cellulosimicrobium-cellulans*, which is a phylogenetic neighbor of *Promicromonospora* (Schumann et al., 2001); secondly, the generic status of *Oerskovia* was reconfirmed and thirdly, *Promicromonospora enterophila* was reclassified as *Oerskovia enterophila* (Stackebrandt et al., 2002).

The Genus *Cellulomonas*

Introduction

The genus *Cellulomonas* originally described by Bergey et al. (1923) was emended by Clark (1952). The unification of *Cellulomonas* and *Oerskovia* was accompanied by the subsequent

emendation of the genus *Cellulomonas* to accommodate organisms with lysine or ornithine as diagnostic diamino acid of the peptidoglycan (Stackebrandt et al., 1982). As already stated by Stackebrandt and Prauser (1991), "The rational [*sic*] for this union was based on an overestimation of phylogenetic relationships between members of these two genera while, at the same time, neglecting the presence of genus-specific chemotaxonomic properties." The phylogenetic analysis of *Promicromonospora enterophila* (Jäger et al., 1983) and of additional strains of *Cellulomonas* and *Oerskovia* has revealed recently that all these organisms containing lysine in the peptidoglycan clustered together with the type strain of *Oerskoviaturbata* and not with the ornithine containing strains of *Cellulomonas* species. This result supported the view that *Cellulomonas* and *Oerskovia* are separate taxonomic entities that can be differentiated not only by phenotypic characteristics but also phylogenetically after inclusion of additional lysine-containing representatives to 16S rDNA sequence analysis (Stackebrandt et al., 2002).

The type species of the genus *Cellulomonas* is *Cellulomonas flavigena* (Bergey et al., 1923). The species *C. biazotea*, *C. cellasea*, *C. gelida*, *C. fimi* and *C. uda* have been members of the genus since their original description (Bergey et al., 1923). The following species were added later: *C. cellulans* (basonym *Nocardia cellulans*) embracing the misclassified species *C. cartae*, *Brevibacterium lyticum*, *Brevibacterium fermentans* and *Oerskovia xanthineolytica* (Stackebrandt and Kandler, 1980a; Stackebrandt and Keddie, 1986), *C. fermentans* (Bagnara et al., 1985), *C. hominis* (Funke et al., 1995), *C. humilata* (Collins and Pascual, 2000), *C. persica* (Elberson et al., 2000) and *C. iranensis* (Elberson et al., 2000).

Abbreviations: DSM, Deutsche Sammlung von Mikroorganismen; and ^T, indicates type strain.

As a result of the unification of the genera *Cellulomonas* and *Oerskovia*, *Cellulomonas* (*Oerskovia*) *turbata* was affiliated to the genus *Cellulomonas* (Stackebrandt et al., 1982). The inclusion of representatives of several newly described genera of the suborder Micrococineae (e.g., Groth et al., 1997a; Groth et al., 1997b; Groth et al., 1999a; Groth et al., 1999b; Martin et al., 1997) and of sequence data of unclassified *Cellulomonas* strains (accession numbers AB023360–AB023367) into phylogenetic analyses based on different treeing algorithms revealed that *C. cellulans* clustered outside the *Cellulomonas* proper. This observation, supported by differences in chemotaxonomic characteristics (e.g., peptidoglycan structure), led to the proposal of the new genus *Cellulosimicrobium* and reclassification of *Cellulomonas cellulans* as *Cellulosimicrobium cellulans*, which is today considered a sister clade of *Promicromonospora* (Schumann et al., 2001).

Phylogeny

Cellulomonas species have been among the first bacteria to be subjected to 16S rDNA cataloguing (Stackebrandt et al., 1980d; Stackebrandt and Woese, 1981), revealing the phylogenetic relatedness to members of *Arthrobacter*, *Micrococcus* and related taxa. This relationship was supported by 5S rDNA analysis performed on *Cellulomonas biazotea* and a variety of coryneform bacteria (Park et al., 1987).

Analysis of the almost complete 16S rDNA sequence of the type strains reveals a high degree of similarity (above 95% similarity; Table 2, upper right triangle). Only the pair *C. biazotea* and *C. fimi* reveals almost identical sequences (99.7%), while most binary values are below 98%. The phylogenetic position determined by use of different treeing algorithms (distance matrix, De Soete, 1983 and Felsenstein, 1993; and neighbor joining and maximum parsimony, Felsenstein, 1993) under the influence of varying reference organisms reveals that the intrageneric branching order is not stable, which is also reflected by the lack of high bootstrap values. This is especially obvious for *C. hominis*, which changes its position significantly and which can even be found as the most deeply branching member of the family, thus making the genus *Cellulomonas* a non-monophyletic taxon. This phenomenon has already been observed by Funke et al. (1995) in the description of *C. hominis*, which branched adjacent to *Oerskovia turbata*. Members of *Cellulomonas* and *Oerskovia* can be distinguished by a set of signature nucleotides of their 16S rDNA sequences (Table 3).

Genomic Relatedness

With binary DNA similarity values of less than 60%, the *Cellulomonas* species investigated can be considered genetically well defined. A few species appear closely related as judged from DNA similarity values around 50%, i.e., *C. biazotea* and *C. fimi* and a cluster comprising *C. uda*, *C. flavigena*, *C. persica* and *C. iranensis* (Fig. 2; Table 2, lower left triangle). Similarity values obtained with different hybridization methods as well as reciprocal values may deviate by more than 30%, but this range does not answer the question of the respective strain's affiliation to a different species.

Taxonomy

Cellulomonads are slender irregular rods (ca. 0.4–0.8 μm in diameter), which may vary considerably in length and which may be arranged in V-formation (Fig. 3). On agar media, they may undergo a more or less expressed morphological growth cycle. In this case, colonies resulting appear nocardioform, i.e., they show mycelia-like fringes. The filaments, which may be branching, fragment subsequently into rods (Fig. 4). Nocardioform mycelia-like structures may also appear when filaments penetrate into the agar medium. Week-old cultures are composed mainly of short rods, but a proportion of the cells may be coccoid. Data on the motility of cellulomonads are inconsistent: *C. fermentans*, *C. flavigena*, *C. cellasea*, *C. humilata* and *C. uda* are the only representatives of the genus which have been reported to be nonmotile (Stackebrandt and Kandler, 1979; Schaal, 1986); however, polar multitrichous flagella were detected also for *C. flavigena*, *C. cellasea* and *C. uda* (Thayer, 1984a).

Physiological Properties

Chemotaxis towards cellobiose and hemicellulose hydrolysis products, e.g., cellotriose, D-glucose, xylobiose and D-xylose, as well as other sugars has been observed in *C. gelida* ATCC 486 (Hsing and Canale-Parola, 1992). Two types of separately regulated cellobiose receptors (Cb1 and Cb2) were described, allowing the motile organism to migrate towards plant-derived cellulose and hemicellulose by swimming up concentration gradients of cellobiose and other sugars. While one receptor Cb1 was inducible and bound to cellobiose and xylobiose, receptor Cb2 was synthesized constitutively and bound to cellobiose, cellotriose, xylobiose and D-glucose. In a following paper, the authors (Hsing and Canale-Parola, 1996) described that L-methionine is required for normal cell motility and chemotaxis and that S-adenosylmethionine

Table 2. DNA-DNA hybridization similarities (lower left triangle) and 16S rDNA similarities (upper right triangle) among type strains of *Cellulomonas* species.

is involved in sugar chemotaxis. Methylation occurred posttranslationally, increased upon addition of sugar attractants, and decreased after removal of the stimulating sugars. The cellulolytic enzymes are controlled by catabolic repression, as activity against carboxymethyl cellulose is only low during growth on glucose or cellobiose (Choi et al., 1978; Stoppok et al., 1982).

All cellulomonads are able to grow under aerobic and microaerophilic conditions, and *C. fermentans* (Bagnara et al., 1985) and *C. uda* ATCC 21399 (Dermoun et al., 1988b) grow under strictly anaerobic conditions as well. Glucose uptake of whole cell suspension of a *C. fimi* isolate was two-fold higher under aerobic conditions than under N₂ or H₂; cellobiose negatively affected glucose uptake (Khanna, 1993).

Fig. 4. Nocardioform microcolony of hyphae of *Cellulomonas blazotea* NCIB 8077 on the surface of Bennett's saccharose agar (28-h slide culture). Bar = 10 µm.

Glucose, maltose and sucrose are fermented by all species, while a few species fermented one or two of the carbohydrates mannitol, xylose, dextrin, β-methyl-xyloside, rhamnose and gluconate. Anaerobically, resting cells catabolize glucose to various endproducts. Performed on a few species, radiorespirometric studies indicated that glucose is catabolized mainly via the Embden-Meyerhof (EM) pathway and, to some extent, through the hexose monophosphate (HMP) shunt (Stackebrandt and Kandler, 1979). This finding is supported by determination of respective key enzyme activities of these pathways in *C. flavigena* (Kim, 1987) and *C. uda* (Marchoun et al., 1987). As shown with *C. flavigena*, gluconate is catabolized via the Entner-Doudoroff (ED) pathway and HMP shunt (Kim, 1987). Endproducts of aerobic glucose dissimilation are mainly CO₂ and either acetate or acetate and L-

lactate (Stackebrandt and Kandler, 1980b). Under anaerobic conditions, resting cells produce mainly CO₂, acetate, lactate, and ethanol as well as smaller amounts of succinate and formate. Similar products, although in varying amounts, were reported for *C. fermentans* (Bagnara et al., 1985) and *C. uda* grown under strictly anaerobic conditions (Marschoun et al., 1987).

Resting cultures of all *Cellulomonas* strains investigated show a highly effective symmetric interchange and an asymmetric redistribution of carbon atoms within the hexose molecule (Stackebrandt and Kandler, 1980b). Under energy excess conditions, *C. uda* accumulates glycogen and trehalose, which in turn are degraded at different rates during carbon starvation (Schimz and Overhoff, 1987a; Schimz and Overhoff, 1987b).

Chemotaxonomic Properties

Cellulomonas species have been extensively characterized with respect to chemotaxonomic properties. The diagnostic amino acid in position 3 of the peptide subunit of the peptidoglycan is ornithine with the interpeptide bridge containing either D-aspartic acid (*C. flavigena*, *C. fermentans*, *C. iranensis* and *C. persica*) or D-glutamic acid (all other species; Table 4). Rhamnose is the major diagnostic cell wall sugar in most strains. Menaquinone MK-9(H₄) is the predominant isoprenoid quinone (Collins and Jones, 1981; Collins and Pascual, 2000). The 12-methyltetradecanoic (*ai*-C_{15:0}) and hexadecanoic (C_{16:0}) acids are the dominant components of fatty acid patterns of cellulomonads, and other branched-chain (e.g., *i*-C_{15:0}, *ai*-C_{17:0}) and straight-chain (e.g., C_{14:0}, C_{15:0}) fatty acids occur in lower amounts (Funke et al., 1995). No data are available on cellular fatty acids of *C. iranensis*, *C. persica* and *C. humilata*. Phosphatidylglycerol (Lechevalier et al., 1981b) as well as diphosphatidylglycerol and a phosphoglycolipid are the major polar lipids (Minnikin et al., 1979). No data are available on isoprenoid quinones and polar lipids of *C. iranensis*, *C. persica*, *C. humilata* and *C. hominis*. The G+C content of the DNA has been determined in several laboratories using different methods. Values ranging between 71.3 and 76 mol% do not allow differentiation of species (Table 5).

Identification

The individual species can be differentiated by a set of characters that require determination of peptidoglycan, cell wall sugars, end products of glucose degradation, and the utilization of certain sugars and acids (Table 4). Compilations of biochemical reactions are given by Stackebrandt

and Kandler (1979), Bagnara et al. (1985), and McHan and Cox (1987). The latter authors propose a simple identification key for most species. Neither genus-specific nor species-specific phages have as yet been detected.

Habitat

The main habitat of cellulomonads appears to be the soil, from which the original cultures were isolated (Kellerman et al., 1913; Kauri and Kushner, 1985; Stackebrandt and Keddle, 1986). This applies also to *Cellulomonas* species described or reclassified recently: *C. persica* and *C. iranensis* were isolated from forest soils (Elberson et al., 2000) and *C. humilata* (basonym *Actinomyces humiferus*) originated from organically rich soils (Collins and Pascual, 2000). Emphasis placed on the cellulolytic activity of these organisms has resulted in the successful isolation of *Cellulomonas* strains from rumen (Lee and Lee, 1986), activated sludge (Ramassamy et al., 1981), and cellulose-enriched environments such as bark and wood (Przybyl, 1979; Deschamps, 1982), coffee cherries (Silva et al., 2000), soils enriched by flax or sisal fibers (Lednicka et al., 2000), and sugar fields (de Leon and Joson, 1980). Cellulolytic culturable bacteria closely related to strains of the genus *Cellulomonas* as revealed by 16S rDNA sequence comparison have been isolated recently from refuse of a landfill (Pourcher et al., 2001) and from an agricultural encatchment (Ulrich and Wirth, 1999). *Cellulomonas hominis* is the first representative of the genus isolated from human clinical samples (cerebrospinal fluid; Funke et al., 1995). Strains of *C. hominis* did not show any cellulolytic activity.

Isolation, Cultivation and Preservation

As described by Stackebrandt and Keddle (1986), a suitable procedure is to enrich cellulomonads in mineral-based medium containing a low concentration (0.05–0.1%) of yeast extract to which filter paper is added as principal carbon source. Isolates are tested on plates containing Avicel, Solka Floc, CF11 cellulose, carboxymethyl cellulose, or phosphoric acid-treated cellulose (Kauri and Kushner, 1985). Cellulose degradation can be visualized owing to the formation of clearing zones. This method is not selective for *Cellulomonas* and isolates must be screened for typical coryneform morphology. Cells are routinely grown in shake flasks at 30°C.

Moderate growth occurs on meat extract agar, peptone agar, or media based on yeast extract or peptone at around neutral pH. Growth-promoting factors in yeast extract are, in part, thiamine and biotin. These factors can be

supplemented by adding a few drops of a sterile commercially available multivitamin solution (e.g., Multibionta and Merck). *Cellulomonas persica* and *C. iranensis* grow on trypticase soy agar at 30°C (<http://www.atcc.org>). *Cellulomonas hominis* can be cultured on Columbia agar (Becton Dickinson Microbiology Systems, Cockeysville, MD, United States) with 5% sheep blood in a 5% CO₂ atmosphere (Funke et al., 1995) or on trypticase soy yeast extract medium at 37°C (<http://www.dsmz.de>). *Cellulomonas humilata* can be cultivated on brain heart infusion agar at 30°C (<http://www.atcc.org>) but does not grow well at 37°C in chemically defined media or in those lacking organic nitrogen and in anaerobic conditions (Collins and Pascual, 2000).

For short-term preservation, stab cultures in semisolid medium should remain viable for several months at room temperature. For long-term maintenance, lyophilization or storage in liquid nitrogen is recommended.

The Glycoside Hydrolases

Of the large variety of hydrolytic starch-, xylan- and cellulose-degrading enzymes detected in cellulomonads, the cellulases are the most salient ones. In a comparative study, *C. biazotea* produced the highest filter-paper cellulase and endo-

glucanase activities, followed by *C. flavigena*, *C. cellasea* and *C. fimi* (Rajoka and Malik, 1997). However, most of the molecular work on cellulase and xylanase genes was determined with *C. fimi* (Table 6). Starch-hydrolyzing activity has been reported in cells of *C. flavigena* (McCarthy and Pembroke, 1988), and the amylase gene product of *Cellulomonas* strain NCIM 2353 has been expressed and characterized (Kumar and Deobakar, 1997).

As summarized by Stackebrandt and Prauser (1991), different kinds of cellulose preparations and derivatives have been tested, including amorphous (Dermoun and Belaich, 1985), swollen, phosphoric-acid-treated (Kauri and Kushner, 1985), microcrystalline (Vladut-Talor et al., 1986; Dermoun and Belaich, 1988a; Poulsen and Petersen, 1988), and carboxymethyl cellulose (CMC). As reported by Kauri and Kushner (1985), degradation of cellulose does not depend on cell-to-fiber contact, but cellulases from three *Cellulomonas* strains were active even when they were physically separated from the fibers. Microcrystalline cellulose (Avicel PH 101, Cellulose MN300, and Whatman grade CC41) appears to be less efficiently attacked than amorphous cellulose (phosphoric-acid-treated Whatman CC41 cellulose; Dermoun and Belaich, 1985). Under anaerobic conditions, celluloses with varying degrees of crystallinity

^aThe database contains information on "*Cellulomonas pachnodae*." The taxonomic status of this species has not yet been described.

were metabolized by *C. uda* ATCC 21399 with the same efficiency as by aerobically grown cells, though the growth yield was reduced significantly (Dermoun et al., 1988b). Optimal liquefaction of carboxymethyl cellulose (CMC) gels occurred in a synthetic medium at 40°C at pH of 7.0–7.5 (Thayer et al., 1984b).

As described in the chapter Cellulose-decomposing Bacteria and Their Enzyme Systems in

Volume 2 (Bayer et al., 2001), the traditional classification of cellulases and other glycosyl hydrolases, based on substrate type and bonds cleaved by a given enzyme, has recently been changed to take account of the common structural fold and mechanistic themes (Coutinho and Henrissat, 1999; <http://www.afmb.cnrs-mrs.fr> Carbohydrate-active enzymes server). Different glycosyl hydrolases are grouped into five families:

Glycoside hydrolase, glycosyltransferase, polysaccharide lyase, carbohydrate esterase and carbohydrate-binding module families, three of which are found in cellulomonads. Whereas in the Second edition, the chapter on the family Cellulomonadaceae emphasized the traditional coverage of individual enzymes and their reactions (Stackebrandt and Prauser, 1991), this chapter highlights the type and activity of enzymes. The results published in the past 10 years of cloning, sequencing, mutagenesis and three-dimensional structure studies have been numerous, and even listing the relevant literature would go beyond the limits of this chapter. Rather, the respective proteins occurring in members of *Cellulomonas*, together with the accession numbers of nucleic acid sequences and protein sequences, are listed and will guide the reader to the relevant literature (Table 6). The information has been taken from the website (<http://www.afmb.cnrs-mrs.fr/~cazy/CAZY/index.html>).

Applications

Cellulomonas strains ATCC 482, ATCC 488, ATCC 491, ATCC 15392 and ATCC 21399 have high protein and essential amino acid values (Dey, 1976), and different strains have been used for single-cell protein production from a variety of waste products, such as sugar cane bagasse (Han et al., 1971; Rodriguez et al., 1993) and rice straw (Han et al., 1971), hemp (Jedar et al., 1987) and ground corn and stalks (Fields et al., 1991). Like other cellulose- and hemicellulose-degrading organisms, *Cellulomonas* strains have been considered potential candidates for waste disposal (Dunlap and Callihan, 1974; Ramasamy et al., 1981) and composting flax and sisal fibers (Lednicka et al., 2000), bagasse (Richard and Peiris, 1981), pith and leaves of sugar cane (Richard and Peiris, 1981; Diaz and Guirola, 1983; Rajoka and Malik, 1986), dried palm oil mill effluent (Agamuthu and Tan, 1985), and shredded newspapers (Rapp et al., 1984) or even as producers of chemicals from low-cost substrates. Mutants of *C. flavigena*, showing elevated xylanase and carboxymethyl cellulase activity, were able to use a larger portion of sugar cane bagasse than their wildtype strains (Ponce-Noyola and de la Torre, 1995; Mayorga-Reyes and Ponce-Noyola, 1998). The isolation of cellulomonads from a landfill of domestic refuse, e.g., *C. fermentans* (Bagnara et al., 1985), *C. hominis*, *C. biazotea*/*C. fimi* and *C. flavigena*/*C. uda* (the latter two pairs of organisms were indistinguishable by numerical analysis) also indicated their potential to degrade solid cellulolytic waste (Pourcher et al., 2001). *Cellulomonas* strain DOT 21, isolated from a domestic refuse (Bichet-Hebe et al.,

1999), has been used to estimate paper degradation by reduction of a whiting fluorescent agent added to white paper prior to the degradation process.

A high number of uncharacterized *Cellulomonas* strains have been isolated from mature coffee cherries of *Coffea arabica* in Brazil (Silva et al., 2000). Under dry conditions, cellulomonads dominated the population of Gram-positive organisms. Their role, however, has not been elucidated.

Cellulomonas flavigena strain HR5, identified by fatty acid analysis, was isolated from agricultural soil in South Korea, contaminated with 4-chlorobenzoate. This plasmid-bearing strain was also able to utilize well 4-bromobenzoic acid, benzoic acid and less well 4-iodobenzoic acid, but not 3-chlorobenzoic acid and 2,4-dichlorophenoxyacetic acid (Yi et al., 2000).

Mixed cultures consisting of *Cellulomonas* sp. ATCC 21399, *Desulfovibrio vulgaris* strain JJ, and *Methanosarcina barkeri* 227 were highly efficient in converting xylan to methane via hydrolysis and acidogenesis (strain ATCC 21399), acetogenesis (strain JJ), and methanogenesis (strain 227; Guyot, 1986). The same *Cellulomonas* strain has also been used in mixed cultures with *Rhodospseudomonas capsulata* to photoevolve molecular hydrogen by the nitrogenase system of the phototrophic strain with cellulose as the sole carbon source (Odom and Wall, 1983).

The ability of cellulomonads to attack cellulose and wheat straw under microaerobic or even anaerobic conditions has been used in mixed cultures to provide nitrogen-fixing strains of *Bacillus macerans* and *Azospirillum brasilense* with energy-yielding products (Halsall and Gibson, 1985; Halsall and Gibson, 1986a; Halsall and Goodchild, 1986b). Good nitrogen-fixing rates have been reported for the pair *Azospirillum brasilense* ATCC 29145 and *Cellulomonas* strain CS117. The latter is a mutant strain selected for its increased production of cellulase and reduced sensitivity to inhibition or repression by accumulated cellobiose and glucose (Haggatt et al., 1978).

Toxicity Evaluation of Cellulomonads

Cellulomonas flavigena ATCC 482, *C. gelida* ATCC 488, *C. uda* ATCC 491, *C. fimi* ATCC 15724 and *Cellulomonas* sp. ATCC 21399 were tested for toxicity by injecting cell extracts as well as viable cells in fertile chicken eggs and some rodents, respectively. Neither were the cell extracts lethal to chick embryos, nor did the viable cells cause generalized or local infections in rats, mice or rabbits. The sexual maturity, fertility and organs of adult rats as well as the vitality of

their progeny were not affected by feeding 10% protein from the test strains (Dey and Fields, 1995). The clinical significance of *C. hominis* (Funke et al., 1995) is unknown.

The Genus *Oerskovia*

Introduction

Motile nocardioform bacteria were reported among others by Topping (1937), Ørskov (1938), and Jensen (1953). Erikson (1954) described "Oerskov's motile nocardia, strain 27" as "*Nocardiaturbata*." Prauser (1967) demonstrated phenetic similarities among 12 isolates from different soils and the type strain of "*Nocardiaturbata*." The species, however, differed significantly from authentic *Nocardia* strains: instead of meso-diaminopimelic acid (the diagnostic amino acid of the peptidoglycan of nocardiae), lysine was found in strains of "*Nocardiaturbata*," and strains were motile by flagellation of fragmented hyphal parts (Sukapure et al., 1970) and by motile spores (Higgins et al., 1967). These properties formed the basis for the description of "*Nocardiaturbata*" as *Oerskoviaturbata* (Prauser et al., 1970), *Oerskovia* being a genus that contained only motile organisms. The genus was emended (Lechevalier, 1972) because the species grew anaerobically on trypticase soy agar as one of 15 media tested, attacked glucose oxidatively and fermentatively, and was catalase-negative when grown under anaerobic conditions.

In the course of the union of the genera *Cellulomonas* and *Oerskovia* the type species of the genus *Oerskovia*, *O. turbata*, as well as a second species, *O. xanthineolytica*, were transferred to the genus *Cellulomonas*. When describing *C. cartae* (ex "*C. cartalyticum*"), Stackebrandt and Kandler (1980a) proposed *O. xanthineolytica* and *Nocardia cellulans* among other taxa as subjective synonyms of *C. cartae*. *Nocardia cellulans* was formally described as *C. cellulans* and consequently the motile strains of *O. xanthineolytica* were combined with nonmotile strains of *C. cellulans* (Metcalf and Brown, 1957), basonym *Nocardia cellulans* (Stackebrandt and Keddie, 1986). Organisms also included in this species were "*Corynebacterium manihot*" (Collard, 1963), *Brevibacterium lyticum* (Takayama et al., 1960), *Brevibacterium fermentans* (Chatelain and Second, 1966), "*Arthrobacter luteus*" (Kaneko et al., 1969), and *C. cartae* (Stackebrandt and Kandler, 1980b). These organisms were united because they shared the peptidoglycan type L-Lys←D-Ser←D-Asp (Seidl et al., 1980; for additional references, see below), were susceptible to *Oerskovia* phages, particularly to those active against *O. xanthineolytica* (Prauser, 1984;

Prauser, 1986), were phenetically similar in numerical taxonomic studies (Bousfield, 1972; Jones, 1975; Seiler et al., 1977; Seiler, 1983), and were genomically closely related as determined by DNA-DNA similarities obtained for *Brevibacterium fermentans*, *C. cellulans*, "*Corynebacterium manihot*," and *O. xanthineolytica* (60–68.1%; Stackebrandt et al., 1980c; Prauser, 1986). Also, comparative 16S rRNA cataloguing revealed a high similarity level for *Nocardia cellulans* and *C. cartae* (Stackebrandt et al., 1980c). *Cellulomonas cellulans* (including the synonym *O. xanthineolytica*) has recently been reclassified as *Cellulosimicrobium cellulans*.

Today, *Oerskovia* and *Cellulomonas* are considered to be well separated, though closely related (Prauser, 1986; Stackebrandt and Prauser, 1991; Funke et al., 1995; Stackebrandt et al., 2002). Supporting arguments are 1) DNA-DNA similarities of only 20 and 26% (Stackebrandt et al., 1980c; Prauser, 1986); 2) 16S rDNA similarities and sets of 16S rDNA signature nucleotides (Stackebrandt et al., 2002) separating members of the two genera; 3) lysine at position 3 of the peptide subunit of peptidoglycan in *Oerskovia* strains, unlike cellulomonads, which have ornithine at this position (Prauser, 1966; Fiedler and Kandler, 1973); 4) insusceptibility of cellulomonads against *O. turbata* phages (Prauser, 1986); 5) differences in the fatty acid patterns (Minnikin et al., 1979), and 6) differences in the formation of mycelia.

Taxonomy

The genus *Oerskovia* has recently been extended by the reclassification of *Promicromonospora enterophila* as *Oerskovia enterophila* and the description of two new species, *O. jenensis* and *O. paurometabola* (Stackebrandt et al., 2002). *Promicromonospora enterophila* has been described for nonmotile strains isolated from feces of a millipede (Jäger et al., 1983). Spores, described to occur in some strains, were killed by heating at 80°C for 5 min (Jäger et al., 1983) and could not be detected in the type strain (Stackebrandt and Prauser, 1991). With respect to the physiological characters (Jäger et al., 1983), *P. enterophila* is closer to *O. turbata* than to the type species *P. citrea*. Furthermore, 16S rDNA analysis places *P. enterophila* next to *O. turbata* (99.6% sequence similarity), and both species share the same peptidoglycan type. *Promicromonospora enterophila* did not group with the type species of *Promicromonospora*, *P. citrea*, and with *P. sukumoe* (Takahashi et al., 1987), which, together with *Cellulosimicrobium cellulans* (Schumann et al., 2001), forms a distinct line of descent within the suborder Micrococccineae. The exclusive susceptibility of *P. enterophila*

strains to *Oerskovia* phages showed them to be definitely members of this genus (Prauser, 1986). As a consequence, *P. enterophila* has been classified as *Oerskovia enterophila* (Stackebrandt et al., 2002). The two new species *O. jenensis* and *O. paurometabola* had been listed as strains of *O. turbata*. A polyphasic taxonomic study, including 16S rDNA sequence analysis and DNA-DNA similarity studies, revealed the distinct taxonomic status of these strains within the radiation of the genus *Oerskovia*.

Phylogeny

Analysis of the almost complete 16S rDNA of the type strains and some related strains revealed a high degree of relatedness (above 98% similarity, Table 7). The phylogenetic position of these organisms within the radiation of *Cellulomonas* species and other representatives of the suborder Micrococcineae, determined by different treeing algorithms (distance matrix, De Soete, 1983 and Felsenstein, 1993; neighbor joining and maximum parsimony, Felsenstein, 1993), reveals that the genus *Oerskovia* appears as a sister clade of *Cellulomonas* in most analyses (Fig. 2). As already mentioned in the introduction to this chapter, some phylogenetic trees place *C. hominis* at the root of the *Oerskovia* lineage. The phylogenetic tree (Fig. 1) displays the relative phylogenetic position of these organisms. Members of *Oerskovia* differ from those of *Cellulomonas* in the presence of several signature nucleotides of 16S rDNA (Table 3).

Genomic Relatedness

Discrimination of the type strains of the four *Oerskovia* species by DNA-DNA hybridization reveals similarity values below 70%, indicative

of members of the same genomospecies (Wayne et al., 1987). Values above 80% indicate that strain DSM 43878 should be considered a strain of *O. turbata*, and strains DSM 46001 and DSM 46097 can be affiliated to *O. jenensis* (Table 7).

Oerskovia strains are well defined by RiboPrinter® analysis (Bruce, 1996; Allerberger and Fritschel, 1999) using the restriction enzyme *Pst*I (Stackebrandt et al., 2002).

Taxonomy

Oerskovia are typical nocardioforms but may show a coryneform appearance depending on the particular strain, the age of the culture, and the external growth conditions. In general, they are characterized by extensively branching vegetative hyphae (ca. 0.5 µm in diameter) that grow on the surface of the agar or penetrate into it. The substrate hyphae fragment into bacillary (Fig. 5) and coccoid or spore-like elements, which can be motile by differently arranged flagella, i.e., subpolar tufts of one to three flagella (Higgins et al., 1967), monotrichous flagella (for short cellular elements), and peritrichous flagella (for longer cells; Sukapure et al., 1970). All elements, motile and nonmotile, resulting from fragmentation may give rise to new mycelia independently of their size. No aerial mycelium is formed. The growth appears bacteroid in smears. Colonies are lemon yellow to whitish. Their consistency is smooth and the surface is glistening with a tendency to dull. Edges show mycelial or at least hyphal character, resembling those of other nocardioforms.

Representatives of the genus *Oerskovia* can be differentiated from members of *Cellulomonas* by the occurrence of L-lysine as diagnostic diamino acid of the peptidoglycan (Table 5). The interpeptide bridge consists of either L-Thr←D-Asp (*O. turbata*) or L-Thr←D-Glu (Table 5).

Fig. 5. Nocardioform fragmentation of hyphae of *Oerskovia-turbata* NCIB10587 on the agar surface of Bennett's saccharose agar (28-h slide culture). Phase contrast. Bar = 10 μ m.

Muramic acid residues of the type species are *N*-acetylated (Uchida and Aida, 1984). The predominating isoprenoid quinone is MK-9(H₄). Phosphatidylglycerol, diphosphatidylglycerol and phosphatidylinositol are the major polar lipids (Komura et al., 1975; Lechevalier et al., 1981b). Major fatty acids are *ai*-C_{15:0} and C_{16:0}, whereas *i*-C_{15:0}, C_{14:0} and *ai*-C_{17:0} occur in smaller amounts (Stackebrandt et al., 2002). Teichoic

acids are lacking (Evtushenko et al., 1984a). The cytochromes belong to the *a*, *b* and *c* types (Seidl et al., 1980). The G+C content of the type strain of *O. turbata* is 70.5 mol% (Table 5).

The set of phages proposed to be specific of the genus *Oerskovia* (Prauser and Falta, 1968; Prauser, 1984; Prauser, 1986; Stackebrandt and Prauser, 1991) needs to be modified, since the phages O5 (DSM 49112) and O13 (DSM 49139) have host strains recently reclassified as *Cellulosimicrobium cellulans* (DSM 43881 and DSM 46215, respectively). Although no studies on the phage susceptibility of members of the family Cellulomonadaceae have been performed recently, it seems to be reasonable to restrict the set on the *Oerskovia*-specific phages O2 (DSM 49109; host *O. turbata* DSM 43878), O3 (DSM 49138; host *O. jenensis* DSM 46000^T), and O6 (DSM 49111; host *O. turbata* DSM 20577^T).

Physiological Properties

Oerskoviae are aerobic to facultatively anaerobic and produce acid from a variety of carbohydrates (Stackebrandt and Kandler, 1980b; Lechevalier and Lechevalier, 1981a). All strains

Table 9. Differentiating phenotypic properties of *Oerskovia* species as determined by API "Coryne."

utilized the following Biolog GP substrates: β -cyclodextrin, dextrin, glycogen, Tween 40, *N*-acetyl glucosamine, D-gluconic acid, α -D-glucose, maltose, maltotriose, mannose, ribose, salicin, sucrose, trehalose, turanose, D-xylose, methyl-pyruvate, glycerol, adenosine, 2-deoxy adenosine, inosine, thymidine, uridine, and adenosine-5'-monophosphate. The following substrates were not utilized by any *Oerskovia* strain: inulin, D-arabitol, melizitose, *p*-hydroxyphenyl acetic acid, α -keto glutaric acid, alanineamide, D-alanine, L-alanine, L-alanyl-glycine, glucose-1-phosphate and glucose-6-phosphate.

API "Coryne" reactions revealed that all strains were positive in the following reactions: oxidase, catalase, nitrate reduction, pyrazinamidase, α -glucosidase, *N*-acetyl- β -glucosidase, β -glucosidase, and fermentation of glucose, ribose, xylose, maltose and saccharose. All strains were negative in the following reactions: pyrrolidonyl arylamidase, β -glucuronidase, and fermentation of mannitol and lactose. Distinguishing properties are indicated in Table 9.

Identification

Oerskoviae can readily be identified by morphological, chemotaxonomic and physiological properties indicated in Tables 5, 8 and 9 and Fig. 5.

Habitat

Oerskoviae were randomly and rarely isolated from various types of soils from different geographical regions, composts, decaying plant materials and occasionally from various clinical specimens (Cruickshank et al., 1979; Reller et al., 1975; Sottnek et al., 1977). *Oerskovia enterophila* constitutes the major part of the actinomycete microflora of the intestines and feces of litter-inhabiting millipedes, e.g., *Chromatoiulus projectus* (Dzingov et al., 1982; Jäger et al., 1983; Szabó et al., 1983; Szabó et al., 1986). The species occurs also in the feces of the cave-inhabiting blind isopod *Mesoniscus graniger* (Bodnar et al., 1989). A large homogenous population of facultatively

anaerobic *Oerskovia*-type nocardioforms was also found in the gut contents of adult specimens of the common earthworm *Lumbricus polyphemus* (Szabó et al., 1986; Ravasz et al., 1987). None of these oerskoviae could be isolated from the surrounding feeding habitats of the animals. Moreover, the inability of the gut and feces nocardioforms to survive in the natural soil and litter habitats could be demonstrated (Márialigeti et al., 1985). However, among 311 culturable cellulolytic bacterial isolates from soil of an agricultural encatchment, 13 strains were found to show 99.6% 16S rDNA similarity to *Promicromonospora* (*Oerskovia*) *enterophila* (Ulrich and Wirth, 1999).

Isolation, Cultivation and Preservation

Selective media have not been reported for the isolation of strains of the genus. Oerskoviae grow on a wide range of media, as do many other soil bacteria. The main problem in their isolation is the exclusion of organisms that cover large areas of the isolation plates, e.g., swarming bacilli, pseudomonads, and hyphal fungi, as well as the suppression of the numerous streptomycetes, which may be confused at first sight with young stages on the isolation plates and which may possibly antagonize the oerskoviae. Procedures and media used for the isolation of members of the genus *Promicromonospora* (Stackebrandt and Prauser, 1991) can also be recommended for oerskoviae. Tapwater agar (1.5% crude agar in tap water; Lechevalier and Lechevalier, 1989) may also be used to isolate oerskoviae.

Applications

Previous work on *Oerskovia* strains has been performed with *O. xanthineolytica* that has been reclassified recently as *Cellulosimicrobium cellulans* (Schumann et al., 2001). This organism produces inducible extracellular enzymes and rapidly degrades walls of various yeasts (Macmillan et al., 1974). The isolation of α -mannosidase from a strain of *Oerskovia* (Bagiyan et al., 1997) has been reported, but the taxonomic affiliation of this strain remains unclear.

Oerskoviae as Pathogens

The pathogenic potential of oerskoviae was first described by Reller et al. (1975). Strains identified as *O. turbata* were frequently isolated from the blood taken from a patient suffering from endocarditis after homograft replacement of the aortic valve. The source of *O. turbata* remained speculative, although contamination of harvested heart valves with *O. turbata* has been reported (Reller et al., 1975). The occurrence of oerskoviae in various clinical sources was documented (Sottnek et al., 1977) when a large number of motile, Gram-positive, nonsporeforming, yellow-pigmented organisms could be allocated to *O. turbata* and to the former *O. xanthineolytica* (now *Cellulosimicrobium cellulans*). Nine of 31 clinical isolates, collected by the Bacteriology Division, United States Centers for Disease Control (CDC) over a period of 20 years, were identified as *O. turbata*. The source of the *O. turbata* isolates was heart tissues, heart valves, blood and tissues. Since no satisfactory case histories for any of the isolates were available, their clinical significance could not be elucidated.

Vancomycin-sensitive *Oerskovia* strains have been frequently isolated from the commensal bowel flora in humans, where they may cause opportunistic infections. The *vanA* gene, coding for vancomycin and teicoplanin resistance, has been sequenced from the clinical isolate *Oerskovia* strain 892 (Power et al., 1995). The sequence of the plasmid-borne gene was found to be highly similar to that of *Arcanobacterium haemolyticum* and *Enterococcus faecium*. Sialidase (neuraminidase) activity has been detected in culture collection strains of *O. turbata* and a strain isolated from a liver abscess (Müller, 1995). Some of the non-type strains have been reclassified as the new species *O. jenensis* (Stackebrandt et al., 2002). Sialidase activity was not detected in *O. xanthineolytica* (*Cellulosimicrobium cellulans*).

The Family Dermatophilaceae

ERKO STACKEBRANDT

The family Dermatophilaceae embraces two genera, *Dermatophilus* and *Kineosphaera*. *Dermatophilus congolensis* was first described by Van Saceghem (1915) as the causative organism of a disease he named successively as “dermatite granuleuse,” “dermatose contagieuse ou impetigo contagieux,” and “dermatose dite contagieuse des bovides, impetigo tropical des bovides.” This acute, subacute or chronic exudative and proliferative skin disease is prevalent in the humid tropics and subtropics and affects more than thirty animal species and man (Zaria, 1993; Table 1), but animals are also affected in countries of the Northern hemisphere. The disease (also referred to as streptotrichosis, pitted keratolysis, strawberry foot rot, lumpy wool, rain scald or dermatophilosis, depending on the host infected and clinical signs) is economically important, occurring in domestic cattle in tropical regions, sheep in high-rainfall areas, and also wild species (see Zaria [1993] for references). Recently, the genus *Kineosphaera* has been included in the family (Liu et al., 2002). *Kineosphaera limosa*, not reported to be pathogenic, has been isolated from a sequential batch reactor running under alternating anaerobic and aerobic conditions to study biological phosphate removal.

Phylogeny

Austwick (1958) described the family Dermatophilaceae to include the two actinomycete genera *Dermatophilus* and *Geodermatophilus*. The classification of these two genera in a family was based on a single but very unique morphological feature, i.e., division in both transverse and longitudinal planes, which leads to the formation of packets or clusters of cuboid cells or cocci. Considering growth characteristics and developmental stages (Luedemann, 1968), as well as chemical properties (Lechevalier and Lechevalier, 1981; Stackebrandt, 1983), the two previously described species *D. congolensis* and *G. obscurus* differ significantly from each other. It was therefore not surprising that these species

are located at different positions in the dendrogram derived from 16S rRNA cataloguing data. While *G. obscurus*, together with *Frankia*, *Modestobacter* (Mevs et al., 2000) and *Blastococcus* species (Ahrens and Moll, 1970; Urzi et al., 2003), constitutes an individual subline of descent (Stackebrandt et al., 1983; Hahn et al., 1989), *D. congolensis* was found to group by itself within a phylogenetically tight but phenotypically broad cluster, which harbors arthrobacteria, micrococci, cellulomonads and relatives, microbacteria, brevibacteria and others. Consequently, the family Dermatophilaceae was redefined (Stackebrandt and Schumann, 2002) to contain *Dermatophilus* as the only genus, embracing two species, *D. congolensis* (Van Saceghem, 1915) and *D. chelonae* (Masters et al., 1995). The type strain of *D. congolensis* has been deposited as ATCC 14637^T = DSM 44180^T = JCM 8106^T = NCTC 13039^T = NRRL B-2350^T. The type strain W16^T of *D. chelonae* is available as ATCC 51576^T = CIP 104541^T = DSM 44178^T = JCM 9706^T.

Analysis of almost complete 16S rRNA gene sequences showed the two type strains of the two described species of *Dermatophilus* to branch within the order Actinomycetales, suborder Micrococcineae. The two type strains share 94.7% sequence similarity, while those with type strains of other genera of the suborder were only 90–92% similar (representatives of *Demetria*, *Dermacoccus*, *Kytococcus*, *Terrabacter* and relatives; see Introduction to the Taxonomy of Actinobacteria in Volume 1 and Liu et al., 2002). Including a varying set of reference organisms, it was noted that the type strains of *D. chelonae* and *D. congolensis* did not consistently group as phylogenetic neighbors. Nevertheless, because of the phylogenetic position, the presence of a defined set of signature nucleotides and common morphological properties the family Dermatophilaceae was described (Stackebrandt and Schumann, 2000).

Kineosphaera limosa DSM 14548^T = JCM 11399^T (strain Lpha5^T) was described for a coccoid organism from activated sludge that showed 94% 16S rRNA gene sequence similarity to *Dermatophilus congolensis* DSM44180^T. Unfor-

Table 1. Habitat and geographic region of recent reports on infections by *Dermatophilus* spp.

Habitat	Geographic region	Reference
Camels	Arabia	Gitao et al., 1998a
Camels	Eastern Sudan	Gitao et al., 1998b

Humans, cattle, buffaloes, goats, horses, and antelopes	India	Pal, 1995
Turtles and tortoises	Zoo, Australia	Masters et al., 1995
Humans	Brazil	Towersey et al., 1993

Unfortunately, the sequence of *D. chelonae* 44178^T was not included in the analysis, even though the sequence of this organism was available at the time of the description of *K. limosa*, giving the impression that the type strain of the latter species branched outside the radiation of the genus *Dermatophilus*. In fact, including sequences of the two type strains of *Dermatophilus*, *K. limosa* DSM 14548^T, and other *Dermatophilus* spp. taken from the EMBL database, it is obvious that *K. limosa* branches within the radiation of the genus *Dermatophilus*. Strain DSM 14548^T clusters with strain Lpha7, another strain from the same activated sludge sample from which strain DSM 14548^T had been recovered (96.9% similarity). Both strains show 95.1–95.9% similarity to *D. chelonae* DSM 44178^T, which indicates a somewhat closer relationship than seen with *D. congolensis* DSM 44180^T (94.0–94.2% similarity). Two other closely related sequences are of the as yet invalid species “*Dermatophilus crocodyli*” (Buenviaje et al., 1998) and a clone obtained from DNA recovered from a microbial community of a laboratory-scale sequence reactor (K. D. Mc Mahon, unpublished observation). The sequence of a strain isolated from a human subgingival plaque defines an individual sublineage (Paster et al., 2001). None of the branches of members of the family Dermatophilaceae is supported by bootstrap values above 70%, and hence the topology of this part of the dendrogram (generated by the additive treeing algorithm of De Soete [1983] on the basis of Jukes and Cantor [1969] correction of binary similarity values) is of little statistical significance.

The presence in strain *Kineospira limosa* DSM 14548^T of 16S rRNA gene signature nucleotides defined for members of the genus *Dermatophilus* (Stackebrandt and Schumann, 2000), common chemotaxonomic properties, and the morphology of cells (e.g., forming clusters of cuboid cells or coccoid strains) support the relationship between members of the two genera.

The natural habitat of *D. congolensis* is the diseased tissue of infected animals. It is found in or upon the integument where it causes a chronic or acute exudative dermatitis. This bacterium, which apparently does not grow saprophytically in nature, has been isolated mainly from cattle, sheep, goats and equines and, less commonly, from other sources—including camels, giraffes, gazelles, rodents, monkeys, a polar bear, seals, pigs, humans and even nonmammalian sources, lizards and turtles (Gordon, 1976; Zaria, 1993; Masters et al., 1995; see Table 1 for recent reports). From a medical point of view, *D. congolensis* is unique in that its natural growth cycle is restricted to the living layer of the epidermis. Attempts to find *D. congolensis* in the soil have been unsuccessful (Roberts, 1967b), probably owing to the inability of the organism to survive outside the host environment, especially under dry conditions.

Strains of the second species, *D. chelonae*, have so far only been reported in the study on the original description (Masters et al., 1995). These strains were isolated from an abscess in a tortoise, skin lesions of a turtle, and a nose scab on a snapping turtle, all from the Perth Zoo, Western Australia.

Streptotrichosis in both wild and domestic animals has been reported from virtually every part of the world (Gordon, 1976; Zaria, 1993). As pointed out by Roberts (1981), the disease tends to be more severe in those domestic animals raised under conditions quite different from those of their natural environment, such as European cattle in tropical Africa or Merino sheep in the wetter parts of Australia. Even indigenous African cattle crossbred with exotic breeds are particularly susceptible to streptotrichosis. Cattle imported to Central Africa have only been maintained successfully in an uninfected condition at closely supervised government establishments (Lloyd, 1976). The disease may have an important economic effect in certain countries, and the

1968 Abidjan Conference on Agricultural Research Priorities for Economic Development in Africa has placed streptotrichosis second only to contagious bovine pleuropneumonia on the list of serious bacterial diseases (Doutre and Orue, 1968). Streptotrichosis has been directly responsible for losses in the production of hides, beef and milk, but losses also result from the disease in infected cattle. Lloyd (1976) and Bwangamoi (1976) discuss the effects of streptotrichosis in livestock in Nigeria and East Africa, respectively, estimating that the disease contributes significantly to the reduction of the value of hides (up to 16% for cattle hides), to the decrease in lactation by sucking calves in the field because of lesions on the udder affecting the teats, and to the reduction in meat production caused by either slaughter or death of animals suffering from severe forms of the disease.

A few human isolates are known, most probably as a result of direct contact with infected animals (Kaplan, 1976). One strain, isolated from a wrist infection of an adult male, is on deposit as ATCC 14639.

Kineosphaera limosa Lpha5^T (DSM 14548^T) and its closest relative, strain Lpha7, were isolated only once from an activated sludge reactor, enriched with 2% phosphorous (Liu, 1995; Liu et al., 2000; Liu et al., 2002). Their involvement in the removal of phosphate is unknown. No information is available about pathogenicity of these organisms.

Isolation

The following procedures and descriptions are basically taken from Roberts (1981), supplemented with information from the volume entitled *Dermatophilus Infection in Animals and Man* (Lloyd and Sellers, 1976).

Dermatophilus congolensis is readily isolated from newly formed scabs by chopping or mincing material from the base of the scab in a small volume of sterile nutrient broth or distilled water and then plating on blood agar (5–10% defibrinated sheep blood in a blood agar base). A modified procedure uses Haalstra's method (Haalstra, 1965), growing the isolates on defibrinated 10% human blood agar plates containing 1000 units of polymyxin B sulfate (Pfizer) per ml of medium. To obtain a high yield of good-sized colonies, the plates are incubated at 37°C for about 2 days in an atmosphere of 10% CO₂ or in a candle jar, followed by a day in air. Under a CO₂ atmosphere, the colonies that are formed are grayish, dry and tough and are firmly attached to the agar by invading hyphae and covered by aerial mycelia, as seen under stereoscopic microscope with lateral illumination. On

brain-heart-infusion medium, strains have a gray-yellow tint, a wrinkled and shiny surface, and either a rough or smooth consistency, depending on the number of filaments and cocci. During the period in air, the superficial part of the colony is thickened by sporulation events, converting it into a moist, mucoid amber- or cream-colored layer. At this stage, motile zoospores and motile oval or coccoid bodies usually less than a μm in diameter can be observed under the microscope. On agar containing sheep blood, colonies will be surrounded by a zone of complete hemolysis, while no hemolysis occurs with medium containing horse blood.

Isolation of *D. congolensis* from old scabs is difficult because of reduced viability of aged cells or contamination of wetted scabs with other bacteria. Roberts (1981) recommends inoculation of the suspended scab material on the scarified skin of guinea pig or sheep and the use of the resulting scabs for unambiguous identification. Zoospores survive under unfavorable conditions and can resist drying. They can withstand heating at 100°C when dried, and they survive in dry scabs at temperatures between 28 and 31°C for up to 42 months.

Strains of *D. chelonae* were isolated on 9% bovine blood agar (in Oxoid Columbia agar base No. 2; Masters et al., 1995). Growth was observed after 2–3 days of incubation at 37°C in the presence of 10% CO₂ or at 27°C in the ambient atmosphere. Growth also occurred in tryptose-phosphate medium supplemented with 10% ovine serum after 3 days at 37°C when the broth was inoculated with a dense suspension of zoospores.

Kineosphaera limosa was isolated on medium GM1 (Liu et al., 1997) at 30°C at pH 7.0. Medium GM1 contains per litre at pH 7.0: glucose 0.5 g, Na-acetate $\times 3 \text{ H}_2\text{O}$ 2 g, peptone 0.5 g, yeast extract 0.5 g, KH₂PO₄ 0.44 g, MgSO₄ $\times 7\text{H}_2\text{O}$ 0.5 g, (NH₄)₂SO₄ 0.5 g, vitamin solution 10 ml, sludge extract (autoclaved and filtered) 100 ml and agar 16 g.

A lytic phage with species-specific activity was isolated from wool samples infected with *D. congolensis*, collected in Western Australia. This phage reduced the cell numbers of *D. congolensis* on infected wool samples and thus has the potential to be used as a biocontrol agent of dermatophilosis (Patten et al., 1995).

Maintenance Medium

Good growth of *Dermatophilus* strains is achieved in the media recommended by both the American Type Culture Collection (medium 44: brain heart infusion agar, Difco 0418) and the German Culture Collection (medium DSM 65:

brain heart infusion, 18.5 g; glucose, 5.0 g; agar, 12 g; and distilled water, 1 liter; or medium 82: glucose, 4 g; yeast extract, 4 g; malt extract, 10 g; agar, 12 g; and distilled water, 1 liter), 1% tryptone with 0.5% sodium chloride, or on trypticase soy broth agar (medium DSM 535), supplemented with 5% blood.

Kineosphaera limosa is maintained on medium DSM medium 776 (Nakamura et al., 1995), containing in grams per liter: glucose, 0.5; peptone, 0.5; yeast extract, 0.5; Na-glutamate, 0.5; KH_2PO_4 , 0.5; $(\text{NH}_4)_2\text{SO}_4$, 0.1; $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 0.1; and at pH 7.0 and 28°C.

Preservation of Cultures

Well-grown cultures in parafilm-sealed Erlenmeyer flasks may be kept at 4°C for several weeks and frozen at -20°C for several months. For lyophilization, good recovery rates are obtained when fresh materials from colonies on blood agar are suspended in nutrient broth. Vanbreuseghem et al. (1976) recommended the following procedure: the bacterial suspension is made in 2 ml of a mixture of equal volumes of ox serum, a 10% solution of sucrose in distilled water, and a 5% solution of neopeptone (Difco) in distilled water. Viable isolates have been maintained in this state for more than 10 years. Subcultures are made by mixing the lyophilized cells with a solution consisting of 2% glucose and 1% neopeptone in tap water. Freeze dried cultures are stored at 8°C.

Identification

Extensive information is only available for *D. congolensis*. Raised scabs from the skin of an animal should immediately suggest a diagnosis of *Dermatophilus* infection, but it is the morphology, i.e., the stages of the life cycle, that makes identification of this organism relatively easy. Smears of scabs, softened with a few drops of physiological saline, may be stained by the Giemsa, methylene blue, or Grocott silver-methenamine method; according to Gordon (1976), the organisms show up well in Gram-stained smears and in hematoxylin- and eosin-stained sections. The most salient characteristics are the branching mycelium, with formation of transverse rows of cocci.

The morphological features of the life cycle of *D. congolensis* have been extensively described by Van Saceghem (1915), Roberts (1961), Gordon and Edwards (1963), and Gordon (1964). Zoospores germinate by budding to produce a germ tube that extends at its growing tip to elongate into filaments. Transverse septation and

branching starts at the other end and consists of the oldest cells of the filament. The structure thickens by division of cells in longitudinal planes. Branches divide at right angles in the same manner as the original filament, giving rise to up to eight parallel rows. In cells enclosed within the epidermis, transverse septation is followed by division exclusively in longitudinal planes, to give each of the original segments of the filament a cross-banded appearance. In liquid growth media, division is not confined so that cuboid packets of cells are formed. When the process of division is complete, the resulting cells separate as fully motile zoospores. These zoospores are enclosed in a thick, irregular mass of capsular matrix that is a degradation product of the cell wall that developed during the divisions of the filament. Zoospores are equipped with from 5 to more than 50 flagella and are isodiametric (Gordon, 1964; Richard et al., 1967; Fig. 2). Certain parts of the life cycle may not occur in artificial culture, depending on the strain investigated and the culture conditions applied (Roberts, 1963). Zoospores of *D. congolensis* are chemotactically attracted to CO_2 , which may facilitate their recovery from lesions and epidermis damage (Roberts, 1962). In the presence of 10% CO_2 and at 37°C, good growth is achieved, but aerial hyphae may not be formed and septation and spore formation are delayed. *Dermatophilus congolensis* (Fig. 2D) differs from *D. chelonae* (Fig. 3) in having a thick capsule surrounding mature filaments and fewer flagella per zoospore (Masters et al., 1995).

All members of the family can be identified by their 16S rRNA gene sequence. *Kineosphaera limosa* differs from dermatophili in the lack of formation of a mycelium and of spores in strain 14548^T (Fig. 4) and in the mol% G+C of DNA (reported to be as high as 71.3 in strain 14548^T, while that of *D. congolensis* DSM 44180^T is only 57–59; Liu et al., 2002). Other differences occur in the composition of the predominant cellular fatty acids (Table 2). Whether strain DSM 14548^T shows typical *Dermatophilus*-like morphology when grown under different conditions and whether the discrepancies in the base composition of DNA are confirmed must await further investigations of these properties.

Different methods have been used to characterize strains of *Dermatophilus congolensis* from various geographic regions and hosts. These methods include:

- 1) Comparison of extracted proteins by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and Western blotting (Makinde and Gyles, 1999). Of different extraction methods used, the separation of lysostaphin-solubilized proteins of whole cells was found suitable for characterization of protein patterns,

Fig. 1. Phylogenetic tree generated on the basis of 16S rRNA gene sequences showing the nearest neighbors of members of Dermatophilaceae. The tentatively named species “*Dermatophilus crocodyli*” strain TVS 96-490-7b (16S rDNA accession number AF226615) branches with strain LBP61 but was not included in the dendrogram because only 1263 bases are available for comparison. Bootstrap value was calculated for 500 replicate trees. The bar corresponds to a 2% difference in nucleotide sequences.

Fig. 3. Morphology of *Dermatophilus chelonae*. A. Thin capsule (0.5 μm thick) around cells of strain W16^T. On scale bar, one division = 10 μm. From Masters et al. (1995) with permission.

Fig. 2. Morphology of *Dermatophilus congolense*. A) Wet mount of beef infusion-peptone broth culture, showing various stages in development, including fine hyphae and multiseptate filaments that transform into chains of coccal packets. Scale bar = 10 μm. B) Wet mount of broth culture, showing fully segmented hyphae with cubical packets of coccoid spores. Scale bar = 5 μm. C) Negative stain (phosphotungstic acid) of an encapsulated motile spore with tuft of flagella. Scale bar = 10 μm. From Gordon (1964) with permission. D) Thick capsule (2 μm thick) around mature filaments of mammalian strain W15. On scale bar, one division = 10 μm. From Masters et al. (1995) with permission.

Fig. 4. Morphology of *Kineosphaera limosa* strain Lpha5^T. A) Scanning electron micrograph. B) Transmission electron micrograph, showing intracellular polyhydroxyalkanoate (PHA) granules. Bar = 1.0 μm. From Liu et al. (2002) with permission.

Table 2. Chemotaxonomic characteristics of genera of the family Dermatophilaceae and related genera.

Genus	Diamino acid	Interpeptide bridge	Major menaquinone(s)	Polar lipids	Predominant cellular fatty acids	Mol% G+C
<i>Dermatophilus</i>	meso-A _{2pm}	None	MK-8(H ₄)	PG, DPG, PI	C _{16:0} , C _{15:0} , C _{14:0}	57–59
<i>Kineosphaera</i>	meso-A _{2pm}	None	MK-8(H ₄)	PG, DPG, PI, PE, PC	C _{16:0} , C _{17:1} , C _{18:1} , C _{17:0}	71.3
<i>Dermacoccus</i>	L-Lys	L-Ser ₁₋₂ -D-Glu or L-Ser ₁₋₂ -L-Ala-D-Glu	MK-8(H ₂)	PI, PG, DPG	<i>i</i> -C _{17:0} , <i>ai</i> -C _{17:0} , <i>i</i> -C _{17:1}	66–71
<i>Kytococcus</i>	L-Lys	D-Glu ₂	MK-8, MK-9, MK-10	PI, PG, DPG	<i>ai</i> -C _{17:0} , C _{17:0} , <i>i</i> -C _{17:1}	68–69
<i>Demetria</i>	L-Lys	L-Ser-D-Asp	MK-8(H ₄)	PI, PE, PG, DPG, PL	C _{18:1} , C _{18:0} , C _{17:0} , <i>ai</i> -C _{17:0}	66

Abbreviations: A_{2pm}, diaminopimelic acid; C_{14:0}, tetradecanoic acid; C_{15:0}, pentadecanoic acid; C_{16:0}, hexadecanoic acid; *i*-C_{16:0}, 14-methylpentadecanoic acid; C_{17:0}, heptadecanoic acid; *i*-C_{17:0}, 15-methylhexadecenoic acid; *ai*-C_{17:0}, 14-methylhexadecanoic acid; C_{17:1}, heptadecanoic acid; *i*-C_{17:1}, 15-methylhexadecenoic acid; C_{18:0}, octadecanoic acid; C_{18:1}, octadecenoic acid; MK-8(H₂) and MK-8(H₄) are partially saturated menaquinone with one or two of eight isoprene units hydrogenated, respectively; MK-9 and MK-10 are unsaturated menaquinones with nine or ten isoprene units, respectively; PI, phosphatidylinositol; PG, phosphatidylglycerol; PC, phosphatidylcholine; DPG, diphosphatidylglycerol; PE, phosphatidylethanolamine; and PL, unidentified phospholipid.

Data from Liu et al. (2000) and Stackebrandt and Schumann (2002) and Introduction to the Taxonomy of Actinobacteria.

leading to the recognition of different electrophoretotypes. Western blotting of different proteins, separated by PAGE with sera from dermatophilosis-infected cattle, demonstrated antigenic relationship between all isolates, leading to the recognition of a prominent common band at 28 kDa.

2) Multilocus enzyme electrophoresis analysis was performed on mainly Australian isolates of *D. congolensis* from warm- and cold-blooded animals (Trott et al., 1995). On the basis of 16 enzyme loci examined, the *Chelonid* isolates grouped differently from the other isolates (these strains were later described as *D. chelonae*). The remaining strains formed two groups that were as distant as those generally found for different species. In each group several subclusters emerged, and in each group α- and β-hemolytic strains were represented. Most of the

non-Australian strains clustered with Australian strains, and most subclusters contain strains from different geographic regions. In conclusion, it was stated that the genetic diversity of *D. congolensis* strains was substantial, confirming results of DNA restriction enzyme analysis.

3) Comparison of riboprints from different *D. congolensis* isolates from one herd in Chad led to the recognition of at least five different restriction fragment length polymorphism patterns, which may partly explain the failure to immunize against dermatophilosis in the field (Faibra, 1993).

4) Analysis of proteases in culture filtrates from *D. congolensis* isolates from different farm animals by substrate (azucasein). SDS-PAGE revealed that bovine isolates contained more proteolytic activity than that of ovine isolates. Serine protease inhibitors had an inhibitory

effect while other classes of proteases had no effect on activity, suggesting that the *Dermatophilus* isolates express a number of alkaline serine proteases (Ambrose et al., 1998).

5) Different DNA isolation protocols were tested for random amplified polymorphic DNA genotyping for isolated of *D. congolensis*. The pattern obtained indicated that genotypic variation between isolates correlated with host species but not with geographic location. Bovine and equine strains appeared more similar to each other than to the ovine strains (Larrasa et al., 2002).

6) Restriction analysis of DNA using the enzymes *Apa*I, *Bam*HI, and *Pvu*II produced profiles that differentiated between *D. congolensis* and *D. chelonae* (Masters et al., 1995).

7) Totally, 120 isolates of *D. congolensis* from equine dermatophilosis were subjected to phenotypic characterization by API ZYM[®] tests, a conventional physiological test, and analysis of membrane protein profiles (Krüger et al. 1998). These tests revealed high similarity in the data obtained, and minor differences did not correlate with the geographic origin of the isolates. Comparison of the API ZYM[®] data with those of Hermoso de Mendoza et al. (1993) revealed similar test profiles. Leucine-arylamidase reacted strongest with the type strain, but esterase (C4), esterase lipase (C8), valine arylamidase, and acid phosphatase also gave distinct reactions with all strains in both studies.

As pointed out in the introduction, dermatophili and *Geodermatophilus obscurus* show striking morphological similarities in certain stages of their life cycles. On the other hand, their differing incompatible ecological niches, together with marked differences in their chemotaxonomic features, colonial pigmentation, location and number of flagella, DNA base composition, mode of branching, and pathogenicity make it easy to clearly differentiate between members of the two genera.

Morphological and chemotaxonomic properties of Dermatophilaceae members are listed in Table 2. Table 3 lists the morphological and physiological properties of members of the family.

Pathogenicity

In principle, sheep and cattle are protected against infection by *Dermatophilus* by the hair coat and dry surface sebum, while the stratum corneum protects uncornified epidermis (Amakari, 1976; Roberts, 1963; Roberts, 1967b). *Dermatophilus congolensis* itself is not highly pathogenic and a combination of factors, such as malnutrition, damage of the skin's defensive barriers, and rainfall, will facilitate infection through

flies attracted by exudates resulting from inflammation caused by arthropods. As summarized by Zaria (1993), growth of *D. congolensis* is inhibited by commensal bacteria, such as *Bacillus* spp. isolated from the skin of healthy sheep, and by coagulase-negative staphylococci isolated from diseased and disease-free pigs; application of antibiotic-producing staphylococci and bacilli to the skin of animals as means of biological control and bacteriotherapy of *D. congolensis* is under discussion (Zaria, 1993).

Zoospores are the principal agents of infection. Spread of infection involving zoospore transfer from wetted scabs to the animal surface is reviewed by Richard and Shotts (1976). It has been observed that introduction of the pathogen into the dermis usually commences during moist atmospheric periods (Roberts, 1967b; see Oppong, 1976) at the sites of trauma, through wounds caused by the activity of biting arthropods, through the contact of plants and animals, and through the sweat ducts and pilosebaceous structures. The main entrance appears to be through hair follicle sheaths, which rupture and allow the organism to spread into the dermis (Amakari, 1976). The odor of cultures of bacteria, including *D. congolensis*, indeed attracts gravid females of the sheep blow fly *Lucilia cuprina* (Morris et al., 1997). *Dermatophilus congolensis* invades only the living layer of the epidermis. From the nature of the skin surface, especially that of cattle, it was deduced that the zoospores require a humid, possibly windswept environment, with a temperature range of 34.5–40°C. In the slightly acidic environment within the epidermis, the organisms proliferate without competing with other microorganisms. Hyphae can be observed in the upper epidermis, especially in the stratum corneum, and within 24 hours of infection the filaments penetrate perpendicularly as far as the epidermal basement membrane (Roberts, 1965; Roberts, 1967b; Zaria, 1993). It is suggested that *D. congolensis* does not penetrate the cellular exudates which separate the infected tissue from the dermal matrix, so that the basement membrane is a natural barrier to penetration. Nevertheless, organisms were seen in the papillary layer of the dermis in those areas where the basement membrane had disintegrated at sites of trauma or when new epidermis became infected by mycelium from hair follicles.

Soon after infection, the invaded cells of the epidermis are covered by one to several layers of laminated scab consisting of cornified epithelial cells and leukocytic cell debris. The characteristic branching mycelium, as well as filaments and zoospores, can be observed in smears of such scabs. Extensive dermal inflammatory reactions are visible on the skin after scabs are removed. New epidermal tissue, formed as a result of cel-

Table 3. Morphological, cultural and physiological characteristics of members of Dermatophilaceae.

Taxon	Morphology	Culture	Physiology
<i>Dermatophilus congolense</i> ^a	Gram-positive branching filaments which divide by transverse and longitudinal septa to form zoospores (5 or more flagella), which form germ tubes, elongate into filaments	On blood agar colonies rough, often becoming viscous, white to gray at first, becoming orange to yellow. Convex colonies with crateriform center may occur. ^d Hemolytic on media containing sheep blood but not horse blood	Acid from glucose and fructose. No acid from lactose, sucrose, xylose, dulcitol, mannitol, sorbitol or salicin. Gelatin and casein hydrolyzed; urease and catalase is produced. Chondroitinase activity against chondroitin 4-sulfate. No hyaluronidase or elastase activity. Nitrate not reduced. Starch hydrolyzed. Susceptible to penicillin, streptomycin, chloramphenicol, erythromycin and tetracyclines. Resistant to antifungal agents
<i>Dermatophilus chelonae</i> ^b	Gram-positive branching filaments which divide by transverse and longitudinal septa to form zoospores (0–6 flagella), which form germ tubes, elongate into filaments. Thin capsule around mature filaments	On bovine blood agar colonies initially dry and adherent, gray white. After transfer to room temperature growth continues, colonies are adherent, white, raised and umbonate or annelliform, becoming sticky after several days. β -Hemolytic on media containing ovine blood; on horse blood nonhemolytic at 37°C and weakly β -hemolytic at 27°C	Acid from glucose, often from fructose and galactose. No acid from lactose, sucrose, xylose, dulcitol, mannitol, sorbitol, trehalose or salicin. Gelatin and casein hydrolyzed; catalase is produced. Urease negative. Chondroitinase activity against chondroitin 4-sulfate. No hyaluronidase or elastase activity. Nitrate weakly reduced to nitrite. Positive lipase activity on tributyrin agar. Susceptible to penicillin, tetracycline, chloramphenicol and sulfafurazol. Resistant to polymyxin, streptomycin and neomycin
<i>Kineosphaera limosa</i> ^c	Gram-positive motile cocci which grow in pairs and packets; nonspore-forming. Polyhydroxybutyrate and polyhydroxyvalerate positive. No accumulation of phosphate	Colonies light-yellow, irregular and umbonate with undulating margins when cells are grown in medium GM1. Hemolysis not reported	Catalase negative, oxidase positive. Obligately aerobic. Nitrate not reduced. Acid not produced. Growth in the presence of up to 3.0% NaCl (w/v)

^aData are from Gordon (1989) and Masters et al. (1995).

^cData are from Liu et al. (2002).

^dZaria (1993) reports on the great variation in the colonial appearance of this species.

lular response, may rapidly be separated from the dermal matrix by invasion of hyphae from infected neighboring follicles (Roberts, 1981). The formation and replacement of keratinic and infected layers of exudated epidermis lead to the formation of massive scabs. The exudates become hard when dry, assuming a paint-brush appearance when it is matted with hair or wool. As discussed by Roberts (Roberts, 1967b; Roberts, 1981) and Oduye (1976), factors limiting the infection are the cellular response and the dermal reactions that are manifested by infiltration of the exudates with lymphocytes, histiocytes and fibroblasts. In animals previously vaccinated, infection ends earlier than in chronic cases, where the cellular response is ineffective even if it is fully developed (Roberts, 1967b).

Besides strains of *D. congolensis* and *D. chelonae*, some *Dermatophilus* strains from lizards have been reported to be pathogenic, one strain

for lizard and mice (Anver et al., 1976), another one for sheep (Simmons et al., 1972). Differences in the lesion caused by these organisms have been reported (Montali et al., 1975).

The pathogenesis of dermatophilosis, however, is not well understood (Zaria, 1993), as virulence factors have not yet been defined. Strains of *D. congolensis* and *D. chelonae* are hemolytic (Skalka and Pospisil, 1992) and produce phospholipases (Masters et al., 1995) and proteolytic enzymes (Gordon, 1964; Roberts, 1965; Ambrose et al., 1998). The characteristics and functions of the proteases are not yet known, and neither is the stage in the life cycle known at which production of these factors is most prominent. The immune response to dermatophilosis (including the role of neutrophils in the killing of spores, the characterization of lymphocyte phenotypes, and the phenomenon of susceptibility to dermatophilosis in animals immunocom-

promised by skin damage and tick [*Amblyomma variegatum*] infestations) has been described in detail by Ambrose et al. (1999).

Successful vaccination against bovine dermatophilosis in southern Chad, using both whole culture and motile zoospores of infective field strains, has been reported by Provost et al. (1976). Systemic antibiotic treatment, including a penicillin and streptomycin combination, has been used in Israel (Nobel, 1976), as well as in Australia where sheep with extensive crusts were made capable of being shorn (Roberts, 1967a). Vaccination is effective against homologous isolates but only partially effective against the challenge of heterologous strains, indicating that immune response may be isolate-specific (How and Lloyd, 1990). Spores and flagella are two of possibly more immunogenic components (Gogolewski et al., 1992). Under laboratory conditions, erythromycin was found to be the most effective antibiotic (Vanbreuseghem et al., 1976). Chemical agents, such as aluminium sulfate, cresol, and copper salts, have been successfully used to treat dermatophilosis in the United Kingdom (Hart et al., 1976). Results of comparative studies—with antibiotics, antiseptics, and miscellaneous compounds applied parenterally and externally—clearly showed the high curative effects of parenteral treatment using antibiotics (Blanchou, 1976).

The Genus *Brevibacterium*

MATTHEW D. COLLINS

Introduction

The genus *Brevibacterium* was established by Breed (1953), with *B. linens* as the type species, for a number of Gram-positive, short, unbranching, rod-shaped bacteria formerly classified in the genus *Bacterium*. Owing to the poor delimitation of the genus, it soon became a repository for a broad range of organisms with very diverse chemical, biochemical and physiological features. Taxonomic studies, in particular those based on cellular chemical analyses, demonstrated the extreme heterogeneity of the genus and resulted in the reclassification of many *Brevibacterium* species in other coryneform genera (including *Arthrobacter*, *Aureobacterium*, *Corynebacterium*, *Curtobacterium*, *Exiguobacterium*, *Microbacterium*, *Nocardioides*, *Oerskovia* and *Rhodococcus*; see Jones and Keddle, 1985). The description of the genus was subsequently tightened and restricted to the species *Brevibacterium linens* and *B. iodinum* (formerly *Chromobacterium iodinum*; Collins et al., 1980). In addition to *B. linens* and *B. iodinum*, several other species have been assigned to the genus in recent years viz., *B. casei* (Collins et al., 1983), *B. epidermidis* (Collins et al., 1983), *B. mcbrellneri* (McBride et al., 1993), *B. otitidis* (Pascual et al., 1996) and *B. avium* (Pascual and Collins, 1999). The seven currently described species form a phenotypically coherent group of organisms, and 16S rRNA gene sequencing studies have shown the genus to be phylogenetically distinct from other actinomycete taxa (Pascual et al., 1996). The intrageneric phylogenetic relationships of the seven currently described species of *Brevibacterium* inferred from 16S rRNA are shown in Fig. 1.

General Characteristics

Brevibacteria exhibit a distinct rod-coccus cycle during growth on complex media. Cells from older cultures (3–7 days) are composed of coccoid cells (ca. 0.6–1.0 μm diameter), whereas irregular, slender rods are characteristic of expo-

nential phase cultures. Both rod and coccoid forms are Gram-positive, but some strains and older cultures decolorize readily. Members are considered nonmotile although sparse flagellation has been reported for *B. iodinum* (Colwell et al., 1969). *Brevibacteria* are nonfastidious, chemoorganotrophic, obligately aerobic (oxidative or indifferent toward sugars), and catalase-positive. All *brevibacteria* are proteolytic, with most strains hydrolyzing casein, gelatin and milk. *Brevibacteria* grow well the presence of 8% NaCl, and many strains also grow in 15% NaCl.

The cell-wall peptidoglycan is the directly cross-linked type based on *meso*-diaminopimelic acid (A2pm; Schleifer and Kandler, 1972). The walls of *brevibacteria* contain complex teichoic acids consisting of neutral sugars, amino sugars and sugar alcohols (Anderton and Wilkinson, 1980; Fiedler et al., 1981). The long-chain cellular fatty acids are primarily of the *anteiso*- and *iso*-methyl branched types, with 12-methyltetradecanoic and 14-methylhexadecanoic acids predominating (Collins et al., 1980; Collins et al., 1983; Bousefield et al., 1983). All *brevibacteria* contain diposphatidylglycerol, phosphatidylglycerol and dimannosyldiacylglycerol as their major polar lipids; some strains also synthesize phosphatidylinositol (Collins et al., 1980; Collins et al., 1983). Menaquinones are the sole respiratory quinones detected in the cellular membrane of *brevibacteria*. Dihydrogenated menaquinones with eight isoprene units (MK-8[II-H₂]) are generally the major component (Collins et al., 1980; Collins et al., 1983). The G+C content of the DNA of *brevibacteria* is 60–67 mol%.

Habitat

Brevibacteria exist in a number of different habitats and especially in those having a high salt concentration. *Brevibacterium linens* is a major component of the microflora of surface-ripened cheese such as Limburger, Romadour, Tilsiter and Stilton (Albert et al., 1944; El-Erian, 1969). *Brevibacterium epidermidis* forms part of the res-

Fig. 1. Dendrogram showing intragenetic phylogenetic relationships within the genus *Brevibacterium* based on 16S rRNA. The tree was constructed using the neighbor joining method (Felsenstein, 1989). Bootstrap values (>90%), expressed as a percentage of 500 replications, are given at branching points.

ident flora of the human skin (Pitcher and Noble, 1978), whereas *B. casei* has been isolated from raw milk, cheese curd and cheddar cheese (Sharpe et al., 1976). The natural habitat of this latter species, however, is uncertain. *Brevibacterium casei* has also been isolated from human clinical specimens and it is now thought that most human strains of brevibacteria in fact correspond to this species (Gruner et al., 1994; Funke et al., 1997). Although *B. iodinum* was originally isolated from milk, its natural habitat is unknown (Davis, 1939).

Brevibacteria have been isolated from habitats other than dairy products and skin. Orange-pigmented strains considered to be very similar to *B. linens* have been isolated from marine fish (Mulder et al., 1966; Crombach, 1974) and seawater (Bousefield, 1978). It is pertinent to note that the species *B. linens* is known to be heterogeneous, consisting of at least two DNA-DNA homology groups (Fiedler et al., 1981). Therefore, orange-pigmented brevibacteria may not necessarily correspond to authentic *B. linens*. Strains of brevibacteria also have been isolated from poultry litter (Schefferle, 1966) and pig manure slurry (Keddie and Cure, 1977). *Brevibacterium otitidis*-like organisms have been found in association with sea mammals (G. Foster, C. Pascual, and M. D. Collins, unpublished data). Brevibacteria have also been recovered from bumble-foot lesions of poultry (Mohan, 1981). These latter organisms have recently been classified as a new species, *B. avium* (Pascual and Collins, 1999).

Clinical Significance

Until relatively recently, brevibacteria have not been associated with human infections. There are, however, now several reports of these organisms from human sources, particularly from skin or structures adjacent to skin (Pitcher and Malnick, 1984; Gruner et al., 1994; Funke and Carlotti, 1994). Diseases reported to be due to brevibacteria include osteomyelitis (Neumeister et al., 1993), continuous ambulatory peritoneal dialysis (CAPD) peritonitis (Gruner et al., 1993;

Hummel et al., 1996), and septicemia (Kaukoranta-Tolvanen et al., 1995; Lina et al., 1994; Reinert et al., 1995). It is now known that organisms formerly referred to as "Centers for Disease Control and Prevention (CDC) groups B-1" and "B-3" from human sources belong to the genus *Brevibacterium* and that most of these correspond to *B. casei* (Gruner et al., 1994). The CDC groups B-1 and B-3 organisms are, however, genetically heterogeneous and there is now evidence of additional unnamed *Brevibacterium* genomospecies having been isolated from human clinical specimens (Gruner et al., 1994). It is pertinent to note that two of the recently described brevibacteria, *B. mcbrellneri* and *B. otitidis*, originated from human sources. *Brevibacterium mcbrellneri* was isolated from infected genital hair of patients with white piedra in association with *Trichosporon beigelii* (McBride et al., 1993), and *B. otitidis* (Pascual et al., 1996) was recovered from human ear infections.

Isolation

Brevibacteria grow well on most peptone-yeast extract based media. Tryptone soya agar supplemented with 4% NaCl (TSAS) is a suitable medium with the following composition (in g/liter): tryptone (Oxoid), 17.0; soya peptone (Oxoid), 3.0; NaCl, 9.0; K₂HPO₄, 2.5; glucose, 2.5; and agar, 12.0. The pH is adjusted to 7.0.

Brevibacteria may be isolated from materials under investigation by streaking or spreading suitable dilutions and incubating at 20–25°C for around 5–7 days. A higher temperature of 30–37°C may be used for skin isolates. For the isolation of *B. linens*, plates should be exposed to light during some period of active growth to enhance pigment formation. A convenient method is to incubate until small colonies are visible and then to remove the plates to a bench exposed to light for the remainder of the period. As the above medium is not selective for brevibacteria, colonies should be examined for a coryneform morphology. Further tests (see below) must be performed to confirm generic and species identification.

Identification

16S rRNA gene sequencing is currently the most reliable means for assigning organisms to the genus and for differentiating between species. There are currently no simple biochemical/physiological criteria for the definitive identification of the genus. *Brevibacteria* exhibit a marked rod-coccus cycle during growth on complex media. Although morphology is a useful initial test, some members of other Gram-positive genera (e.g., *Arthrobacter*, *Microbacterium*, *Corynebacterium* and *Gordona*) also exhibit this morphology. Chemical tests can, however, be used to distinguish *brevibacteria* from these and other actinomycete taxa.

The detection of *meso*-A₂pm in cell wall or whole-cell hydrolysates serves to distinguish *brevibacteria* from the majority of other coryneform and actinomycete taxa. Members of the genera *Corynebacterium*, *Gordona* and *Rhodococcus* also contain walls based upon *meso*-A₂pm. *Brevibacteria*, however, differ from these genera in lacking mycolic acids, possessing predominantly *iso*- and *anteiso*-methyl branched fatty acids, and lacking phosphatidylinositol dimannosides (Collins et al., 1980; Collins et al., 1983). *Brevibacteria* contain wall teichoic acids (Fiedler et al., 1981; Anderton and Wilkinson, 1980; Anderton and Wilkinson, 1985). These compounds also serve to distinguish *brevibacteria* from a host of other taxa. Characteristics useful in distinguishing *Brevibacterium* from other actinomycete and coryneform genera are shown in Table 1.

Although 16S rRNA gene sequencing is currently the most reliable means for identifying *brevibacteria* to the species level, this can also be

achieved, albeit to a lesser degree of confidence, using phenotypic criteria. *Brevibacterium linens* is most easily recognized by producing yellow to deep orange smooth colonies (Mulder et al., 1966; Jones et al., 1973), but it is important to bear in mind that the species is genomically heterogeneous. The color reaction of *B. linens* with various chemical reagents has been used as a taxonomic tool for the differentiation of *B. linens* from other coryneform species (Grecz and Dack, 1961), but this is not exclusively selective (Jones et al., 1973). The pigments of *B. linens* have been shown to consist of the aromatic carotenoids 3,3'-dihydroxy-isorenieratene, isorenieratene and 3-hydroxy-isorenieratene (Kohl et al., 1983). In contrast to colonies of *B. linens*, the colonies of *B. iodinum* are characterized by the production of very distinctive purple extracellular crystals of iodinin (Davis, 1939; Clemo and Daglish, 1950; Sneath, 1960). *Brevibacterium mcbrellneri* produces dry friable contoured colonies, whereas the other described species of the genus (viz., *B. avium*, *B. casei*, *B. epidermidis* and *B. otitidis*) generally produce smooth colonies that are whitish-gray in color. To identify *brevibacteria* to the species level using phenotypic tests, a combination of biochemical and physiological criteria is necessary. Some tests that are useful in differentiating the currently described species of the genus are shown in Table 2.

Production of Bacteriocins and Antimicrobials

Brevibacterium linens has been reported to produce a variety of bacteriocins and antimicrobial substances. Some strains of *B. linens*

Table 1. Differentiation of *Brevibacterium* from other actinomycete and coryneform genera.

Genus	Morphology	Wall diamino acid	Arabinogalactan polymer	Mycolic acids	Fatty acid type	Major menaquinone
<i>Brevibacterium</i>	Marked rod-coccus cycle	<i>meso</i> -A ₂ pm	—	—	S,A,I	MK-8(H ₂)
	Marked rod-coccus cycle	Lysine	—	—	S,A,I	MK-9(H ₂) or MK-8/MK-9
<i>Cellulomonas</i>	Irregular rods, some coccoid forms	L-Omithine	—	—	S,A,I	MK-9(H ₄)
<i>Clavibacter</i>	Irregular rods	Diaminobutyric	—	—	S,A,I	MK-9,MK-10
<i>Corynebacterium</i>	Irregular rods	<i>meso</i> -A ₂ pm	+	+	S,U,(T)	MK-8(H ₂), MK-9(H ₂)
<i>Curtobacterium</i>	Irregular rods	D-Omithine	—	—	S,A,I	MK-9
<i>Gordona</i>	Rod-coccus cycle	<i>meso</i> -A ₂ pm	+	+	S,U,T	MK-9(H ₂)
<i>Microbacterium</i>	Irregular rods, some coccoid forms	Lysine	—	—	S,A,I	MK-10, MK-11, MK-12
<i>Rhodococcus</i>	Rods and coccoid forms	<i>meso</i> -A ₂ pm	+	+	S,U,T	MK-8(H ₂)

Symbols: +, present; and —, absent.

Abbreviations: S, straight-chain saturated; A, *anteiso*; I, *iso*; T, tuberculostearic acid; (T), tuberculostearic acid variable; MK-8-12, menaquinones with 8–12 isoprene units; MK-8(H₂) and MK-9(H₂), dehydrogenated menaquinones with 8 and 9 isoprene units, respectively; and A₂pm, diaminopimelic acid.

Table 2. Tests useful for differentiating species of the genus *Brevibacterium*.

Characteristics	<i>B. linens</i>	<i>B. iodinum</i>	<i>B. casei</i>	<i>B. epidermidis</i>	<i>B. mcbrellneri</i>	<i>B. otitidis</i>	<i>B. avium</i>
Colony morphology and consistency	Smooth, creamy	Smooth, creamy	Smooth, creamy	Smooth, creamy	Contoured friable, dry	Smooth, creamy	Smooth, creamy

Mannitol	V ⁽⁻⁾	-	-	+	-	-	+

Symbols and Abbreviations: +, positive; -, negative; V, variable; V⁽⁻⁾, variable with most negative; V⁽⁺⁾, variable with most positive; and W, very weak growth. Data from Jones and Keddie (1986), McBride et al. (1993), Funke and Carlotti (1994), Pascual et al. (1996), Pascual and Collins (1999).

produce a bacteriocin, Linecin A, which is inhibitory to some other *B. linens* strains but not to other species of the genera *Brevibacterium*, *Corynebacterium* and *Micrococcus* (Kato et al., 1991). A bacteriocin designated "Linocin M18," with a broad activity spectrum (active against species of the genera *Arthrobacter*, *Bacillus*, *Corynebacterium*, *Micrococcus* and *Listeria*), has been characterized from a strain of *B. linens* (originating from the surface of red smear cheese; Valdes-Stauber and Scherer, 1994). An antimicrobial substance, designated "Linenscin OC2," which is different from Linecin A and Linocin M18, has been isolated from *B. linens* strain OC2 (Maisnier-Patin and Richard, 1995). Linenscin OC2 is inhibitory towards food-borne pathogens such as *Staphylococcus aureus* and *Listeria monocytogenes*, but not against Gram-negative bacteria. *Brevibacterium linens* strains (isolated from brine used to salt red smear cheese) have also been shown to produce an antimicrobial agent against *Listeria* species (Martin et al., 1995). Similarly, Ryser et al. (1994) isolated from cheese an orange coryneform resembling *B. linens* that produces a bacteriocin-like agent inhibitory for listeriae.

Applications

Brevibacterium linens and other *B. linens*-like organisms are residents of the exterior of surface-ripened soft cheese of the Limburger variety, where they are considered to contribute to the surface color and ripening (Albert et al., 1944; El-Erian, 1969; Eliskases-Lechner and Ginzinger, 1995; Valdes-Stauber et al., 1997). *Brevibacterium linens* and some other brevibacteria produce methanethiol from L-methionine (Sharpe et al., 1976; Sharpe et al., 1977). Methanethiol is an important constituent of the aroma of cheddar cheese, and it is thought that the production of this compound by *B. linens* and related organisms may contribute to the

aroma and flavor of surface-ripened cheeses such as Limburger and Romadour. Historically, *B. linens* was considered to be the bacterium solely responsible for ripening of bacterial smear-ripened cheese, but other brevibacteria, micrococci and coryneforms are also of importance.

In addition to the commercial production of *B. linens* for use as a cheese-ripening agent, several patents have been published involving the use of brevibacteria in biotechnological applications, including wastewater treatment, vitamin production, and pharmaceutical processes (Anonymous, 1987, 1988, 1990, 1991; Farrar and Flesher, 1989).

Plasmids and Gene Sequence Information

A multicopy plasmid of size 7.75 kb, designated "pBL100," has been isolated from *B. linens* CECT 75 (Sandoval et al., 1985). A plasmid designated "pBL33" has been isolated from *B. linens* ATCC 9174, which has a size of 7.5 kb and a similar restriction map to that of pBL100 (Kato et al., 1989). Holtz et al. (1992) purified plasmids pBL100 and pBL 33 from *B. linens* ATCC 9174 and DSM 20158. Phenotypic studies indicated resistance to kanamycin is possibly conferred by pBL100 but not by pBL 33. Some strains of *B. linens* do not contain plasmids.

Very little gene sequence information is available on authentic species of the genus *Brevibacterium*. Although many sequence entries are present in the European Molecular Biology Laboratory (EMBL)/GenBank under *Brevibacterium*, the great majority of these derive from species that are not genuine members of the genus. Most available *Brevibacterium* sequence data correspond to that of small subunit rRNA. Extensive complete 16S-23S ribosomal RNA data exist on multiple strains of *B. linens*, although comparative data for other *Brevibacterium* species are not available. There is a paucity of other sequence information, and of that which is available, all pertains to *B. linens* (see Table 3).

Table 3. Gene sequence information on *B. linens*.

Gene/sequence	Accession number(s)
Complete ribosomal RNA operon	U59265-U59268, U62440, U62441, U58866, U62524, U90442, U90443
Insertion sequence (IS)-like element	AFO52055
23S rRNA gene insertion sequence	M85098
Insertion sequence IS5 transposase	AF195203
Tuf gene (elongation factor TU)	X76863
LinM18 gene (linocin M18)	X93588
Plasmid LIM complete sequence	AY004211
Plasmid pBL-A8 gene encoding Rep protein	Y11902
Plasmid pRBL1	U39878
Gene for 1,4-butanediol diacrylate	AB020733
TmpA, a putative efflux protein gene	AF030288

The Family Microbacteriaceae

LYUDMILA I. EVTUSHENKO AND MARIKO TAKEUCHI

Introduction

The family Microbacteriaceae (Park et al., 1993; Stackebrandt et al., 1997) embraces a large group of predominantly aerobic Gram-positive bacteria of high G+C content that are distinguished from other actinobacteria by a combination of their unusual B group cell wall peptidoglycan and unsaturated respiratory menaquinones. The bacteria vary in cell morphology, extending from coccoid, small irregular rods to branched fragmenting hyphae. They are spread in various terrestrial and aquatic ecosystems and can be associated with plants, fungi, animals and clinical specimens (Collins and Bradbury, 1992; Funke et al., 1997; Glöckner et al., 2000). Several species and subspecies of the family include either plant pathogens or organisms for which plant pathogenicity has been suggested (Young et al., 1996; Young et al., 2000). The family is a member of the order Actinomycetales, class Actinobacteria (Stackebrandt et al., 1997), and currently harbors 15 genera: *Agreia*, *Agrococcus*, *Agromyces*, *Clavibacter*, *Cryobacterium*, *Curtobacterium*, *Frigoribacterium*, *Leifsonia*, *Leucobacter*, *Microbacterium*, *Mycetocola*, *Okibacterium*, *Plantibacter*, *Rathayibacter* and *Subtercola*. Furthermore, a number of other microorganisms of the family were reported or can be suggested by 16S rRNA gene sequence analyses to represent separate lines of descent and may be nuclei of new genera. Those include “*Brevibacterium helvolum*” DSM 20419 (Rainey et al., 1994), “*Corynebacterium bovis*” ATCC 13722 (Watts et al., 2001), some copiotrophic bacteria (Iizuka et al., 1998), “*Cryocola antiq-uus*” (Kochkina et al., 2001; Gavrish et al., 2003), glacial ice microorganisms (Christner, 2002), fresh water ultramicrobacteria (Hahn et al., 2003) and some others. The history, classification, ecology and other information on the organisms of the validly described genera are reviewed in 15 sections, followed by a brief characterization of some bacteria that are waiting for their valid description as new genera.

The current classification system of the family Microbacteriaceae and the genera it comprises is

a good example of the use of a classification strategy based on a polyphasic approach to taxonomy (Colwell, 1970). Determination of cell and cell wall components (Schleifer, 1970; Yamada and Komagata, 1970; Yamada and Komagata, 1972a; Yamada and Komagata, 1972b; Schleifer and Kandler, 1972; Yamada et al., 1976; Keddies and Cure, 1977; Keddies and Cure, 1978; Uchida and Aida, 1977; Minnikin et al., 1978; Collins et al., 1979; Collins et al., 1980b; Collins et al., 1982b; Collins et al., 1983c; Collins et al., 1983d; Collins and Jones, 1980a; Collins and Jones, 1981; Collins and Jones, 1983b; Goodfellow and Minnikin, 1985) played the most important role in development of the classification of the bacteria constituting the family Microbacteriaceae in the “nonmolecular” era. Bacteria of the family have group B-type cell wall peptidoglycan (Schleifer and Kandler, 1972), which is characterized by a crosslinkage between the α -carboxyl group of D-glutamic acid in position 2 of the peptide subunit and the C-terminal D-alanine of an adjacent subunit. A diamino acid such as 2,4-diaminobutyric acid (DAB), lysine or ornithine is always present in the interpeptide bridge of this peptidoglycan and can also occupy the third position of the tetrapeptide subunit. In contrast, most other eubacteria have A-type peptidoglycans, in which the crosslinkages bind the ω -amino group of the diamino acid in position 3 of the peptide subunit to the carboxyl group of the C-terminal D-alanine in position 4 of the adjacent peptide subunit (Schleifer and Kandler, 1972). Typical bacteria with the group B-type peptidoglycan, unsaturated respiratory menaquinones, and other associated chemotaxonomic properties clustered together in one or more closely related groups on the basis of early phylogenetic studies, e.g., oligonucleotide cataloging (Stackebrandt et al., 1980), DNA-rRNA cistron similarities (Döpfer et al., 1982), 5S ribosomal RNA sequence similarities (Park et al., 1987), and similarity values of an insertion sequence within the 23S rRNA gene (Roller et al., 1992).

In 1993, Park et al. analyzed the 5S ribosomal RNA sequences for a large set of bacteria with

the B-type peptidoglycan along with other actinomycetes and concluded that the sequence similarity and associated chemotaxonomic characteristics provide compelling grounds for classifying all actinomycetes with a group B-type peptidoglycan in a single family. The authors established the family Microbacteriaceae that included the type genus *Microbacterium* and the genera *Agromyces* (Gledhill and Casida, 1969; Zgurskaya et al., 1992), *Curtobacterium* (Yamada and Komagata, 1972b), *Aureobacterium* (Collins et al., 1983c), and *Clavibacter* (Davis et al., 1984b), which had been described at that time. In 1997, Stackebrandt et al. outlined the skeleton of a hierarchic classification of actinobacteria based on analyses of 16S ribosomal RNA and the distribution of signature nucleotides and added the genera *Agrococcus* (Groth et al., 1996) and *Rathayibacter* (Zgurskaya et al., 1993b) to the family Microbacteriaceae. The following pattern of 16S rDNA signature nucleotides was proposed as characteristic of the family: nucleotides at positions 45-396 (U-A), 144-178 (C-G), 258-268 (A-U), 497 (A), 615-625 (A-U), 694 (G), 771-808 (G-C), 839-847 (G-U), 1256 (G), 1310-1327 (A-U), and 1414-1486 (U-A; Stackebrandt et al., 1997). About that time, the genera *Leucobacter* (Takeuchi et al., 1996) and *Cryobacterium* (Suzuki et al., 1997) were added to the family, which has since been enlarged by several new genera: *Frigoribacterium* (Kämpfer et al., 2000), *Leifsonia* (Evtushenko et al., 2000; Suzuki et al., 1999), *Subtercola* (Männistö et al., 2000), *Mycetocola* (Tsukamoto et al., 2001), *Agreia* (Evtushenko et al., 2001), *Okibacterium* (Evtushenko et al., 2002), and *Plantibacter* (Behrendt et al., 2002). Figure 1 shows the phylogenetic tree based on 16S rRNA gene sequences, indicating the positions of the current 15 genera and species of the family Microbacteriaceae. Typical cultural, morphological, and chemotaxonomic characteristics of the genera are presented in Table 1.

From the Table and the above-mentioned publications dealing with descriptions of the genera and species of the family Microbacteriaceae, it may be generalized that the family embraces mesophilic or psychrophilic bacteria, which are obligately aerobic to facultatively anaerobic, nonsporeforming organisms with varying cell morphology, ranging from coccoid, small irregular rods to branched fragmenting hyphae. All members of the family contain the group B-type peptidoglycan with varying diamino acids (DAB, lysine or ornithine) and varying structures of the polymers. Mycolic acids and arabinogalactan are not present. All strains are characterized by major unsaturated respiratory menaquinones with isoprene units ranging from 9 to 14 and predominant saturated *anteiso*- and *iso*-methyl

branched fatty acids. Phosphopids are mainly diphosphatidylglycerol, phosphatidylglycerol, and a variety of glycolipids. The G+C content of the DNA is 65–78 mol%.

The Genus *Agreia*

The genus *Agreia* was proposed for the type species *Agreia bicolorata*, an aerobic coryneform actinobacterium with an unusual peptidoglycan containing both DAB and ornithine as diamino acids (Evtushenko et al., 2001), isolated from plant galls induced by nematodes of the subfamily Anguininae (Evtushenko et al., 1994).

When the description of the genus *Agreia* was in press, the description of a new species similar to *Agreia* in the peptidoglycan and menaquinone compositions was submitted (Behrendt et al., 2002). Unaware of the description of *Agreia*, the authors classified the strains as *Subtercola pratensis* and emended the description of the genus *Subtercola*. Though the 16S rRNA gene similarity between the new and the described *Subtercola* species was high and the branching topology was supported by high bootstrap values, the phylogenetic and chemotaxonomic similarity between *Subtercola pratensis* and *Agreia bicolorata* (Fig. 1; Table 1) became obvious once both species had been published. Recently, *Subtercola pratensis* has been reclassified as *Agreia pratensis* (Schumann et al., 2003).

Phylogeny

Bacteria of the genus *Agreia* form a tight phylogenetic cluster with a 100% bootstrap confidence level. The closest phylogenetic neighbor of the genus *Agreia* is the genus *Subtercola* (Fig. 1). Strains of *Agreia* show high 16S rDNA sequence similarities (up to 97%) with organisms of the genus *Subtercola* which are approximately of the same level as reported for several other closely related genera in the family Microbacteriaceae, e.g., *Clavibacter*, *Rathayibacter* and *Frigoribacterium* (Kämpfer et al., 2000), or in other actinomycete families (Prauser et al., 1997; Labeda et al., 2001; Lee and Hah, 2002).

Taxonomy

Bacteria of the genus *Agreia* are aerobic, catalase-positive, and characterized by round, glistening, opaque, butyrous, sometimes fluid colonies, usually yellow or yellow-orange in young cultures and becoming red-orange or brown-orange in some strains with age. The cells are nonsporeforming, irregular rods; primary branching may be rarely observed. In older cultures, shorter irregular rods usually

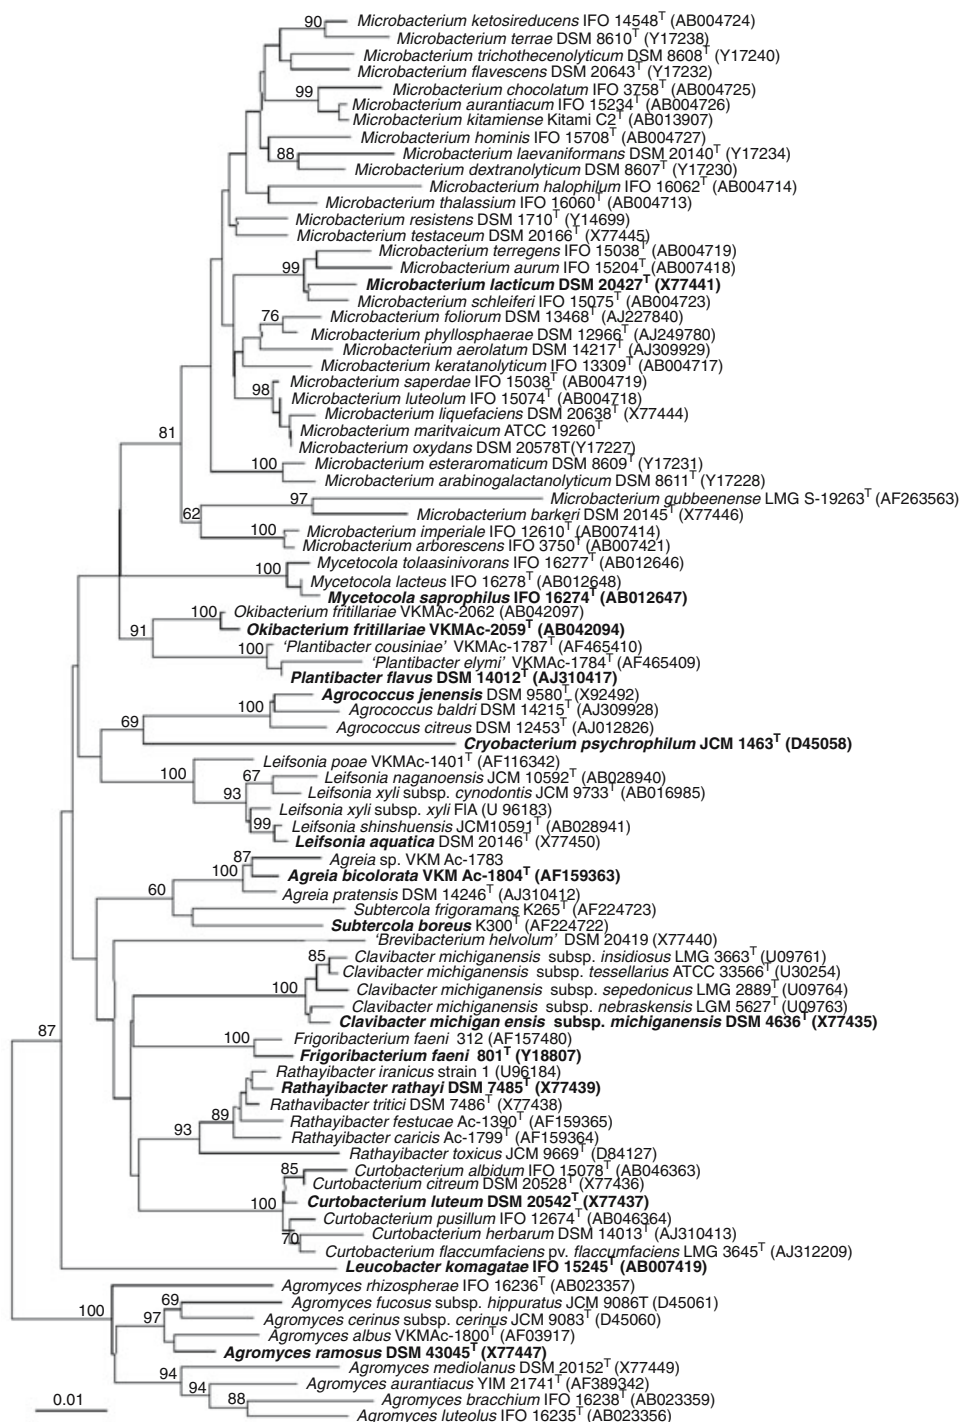

Fig. 1. Phylogenetic tree based on 16S rRNA gene sequence analyses, indicating the positions of 15 genera of the family Microbacteriaceae. The type strains of type species of the genera are given in bold. The tree was generated by the neighbor-joining algorithm (Saitou and Nei, 1987) using Knuc values (Kimura, 1980). The sequence of *Brevibacterium linens* DSM 20425T (X77451) served as an outgroup sequence. The numbers on the tree indicate the percentages of bootstrap samplings (Felsenstein, 1985), derived from 1000 replications. Bar, 1 nucleotide substitution per 100 nucleotides.

^aBranching occurs in the early growth phase (Suzuki et al., 1997).
^bYoung cells of *S. frigoramans* are frequently swollen at the pole or in the middle (Männistö et al. 2000).
^cAll organisms also contain alanine, glutamic acid and glycine; there are no available data on DAB isomers in *Subtercola* and the configuration of lysine in *Mycetocola* and *Okibacterium*.
^dParentheses indicate that a compound varies between strains or species.
^ePeptidoglycan type is abbreviated as indicated by Schleifer and Kandler (1972).
^fMenaquinone type is abbreviated as indicated by Collins and Jones (1981).
^gThe distribution of major menaquinone among different species is given in Table 11.
^hCh, cyclohexyl fatty acids; other fatty acids are abbreviated as indicated by Collins et al. (1980b).
Data from Yamada and Komagata (1970; 1972a; 1972b), Collins and Jones (1980a), Collins et al. (1980b), Davis et al. (1984b), Zgurskaya et al. (1992; 1993b), Yokota et al. (1993a; 1993b), Groth et al. (1996), Suzuki et al. (1996; 1997; 1999), Takeuchi et al. (1996), Takeuchi and Hatano (1998a; 1998b; 2001), Matsuyama et al. (1999), Schumann et al. (1999), Wieser et al. (1999), Evtushenko et al. (2000; 2001; 2002, submitted), Kämpfer et al. (2000), Männistö et al. (2000), Behrendt et al. (2001; 2002), Tsukamoto et al. (2001), Zlamala et al. (2002a; 2002b), and Li et al. (2003).

predominate; pairs or short chains with diphtheroid arrangements are also observed. A marked rod-coccus growth cycle does not occur. Members of the genus *Agreia* possess an unusual peptidoglycan containing two diamino acids, L-DAB and D-ornithine, and also alanine, glycine, glutamate and hydroxyglutamate. Muramic acid of the peptidoglycan is acetylated. The major menaquinone of respiratory chain is MK-10. The principal phospholipids are phosphatidylglycerol and diphosphatidylglycerol. The major fatty acids are *anteiso*-15:0, *anteiso*-17:0 and *iso*-16:0; 1,1-dimethoxy-*anteiso*-pentadecane occurs in the whole-cell methanolysate. The G+C content of DNA is 65.0–67.0 mol% (Evtushenko et al., 2001; Behrendt et al., 2002; L. I. Evtushenko and M. Takeuchi, unpublished observation).

Currently, the genus contains two validly described species, *Agreia bicolorata* (Evtushenko et al., 2001) and *Agreia pratensis* (Schumann et al., 2003).

Habitat

The data available suggest that the main natural habitat of *Agreia* is plant material. *Agreia bicolorata* was isolated from leaf galls induced by the plant parasitic gall-forming nematode *Heteroanguina graminophila* (the subfamily Anguininae) on its host plant, *Calamagrostis neglecta* (Ehrh.) P. Gaertn. et al. (Evtushenko et al., 1994; Evtushenko et al., 2001). There is some evidence that *Agreia bicolorata* might be a particular nematode associate, like *Rathayibacter* spp. (Riley and Ophel, 1992; Zgurskaya et al., 1993b), carried by nematodes into plants and developing inside plant galls induced by the nematode (Price et al., 1979; Bird, 1981). Strains of *Agreia bicolorata* represent a significant portion of bacterial isolates grown from the leaf gall of narrow reed grass collected in vicinity of Moscow, Russia, and were not observed in the same plants free of nematode infection (Evtushenko et al., 1994; Evtushenko et al., 2001). They also produced abundant polysaccharide slime, which is thought to be one of the characteristic features of nematode-associated bacteria (Bird, 1985). On the other hand, *Agreia bicolorata* may be a secondary settler of the galls (their surface sections), descending from the microbial communities of the phyllosphere or plant tissue. One strain similar to *Agreia bicolorata* was found in stem galls induced by *Anguina agropyri* on *Elymus repens* (L.) Gould collected in the same site (Evtushenko et al., 1994). In addition, yellow-pigmented bacteria of this genus, belonging to other genomic groups, were isolated from the same plants, *Calamagrostis neglecta* and *Elymus repens*, infected by the same nematodes and in other plants without visible nematode infestation

(Dorofeeva et al., 1999; Shramko et al., 1999; L. I. Evtushenko and M. Takeuchi, unpublished observation). The yellow-pigmented strains of *Agreia* were not predominant among other coryneform bacteria revealed by the plating technique. The species *Agreia pratensis* was also isolated from grass (Behrendt et al., 2002; Schumann et al., 2003).

Isolation

Organisms of the genus *Agreia* can be isolated from the grasses and related sources listed in the previous subsection. The approaches described by Dunleavy (1989), Behrendt et al. (1997), and Zinniel et al. (2002) for isolation of bacteria from plants may be applied. The following procedure of preparing a sample for isolation of bacteria from plant galls may be used.

The galls are cut from a plant with a sterile scalpel, treated by a detergent or sterilized or both, washed by sterile water, and pre-incubated in water or in any diluted nutrient media for 1–2 h. Then, the galls are cut into pieces, added to 1–2 ml of 0.85% solution of NaCl (w/v), and ground with a pestle. The obtained suspensions of galls are plated onto an appropriate medium. The strains of *Agreia bicolorata* were first isolated using NWG agar (peptone, 2 g; glucose, 1 g; casein peptone, 1 g; glycerol, 10 ml; wort (a liquid formed by soaking mash in hot water), 100 ml; CaCO₃, 5 g; distilled water, 900 ml; agar, 15 g; pH 7.2–7.4) at room temperature (17–24°C; Evtushenko et al., 1994; Evtushenko et al., 2001). Bacteria of this genus can also be isolated and grown on *Corynebacterium* (CB) agar, R2A agar (Difco) and some other media appropriate for isolation and cultivation of plant-associated actinobacteria. The colonies of *Agreia bicolorata* can be recognized owing to their semiliquid consistency and yellow or orange pigment, becoming brown-orange with age on CB agar and some other media. The yellow-pigmented colonies of members of this genus are indistinguishable from colonies of many other coryneform bacteria originating from plant sources.

Corynebacterium (CB) Agar

Glucose	5 g
Yeast extract	5 g
Casamino acids	10 g
NaCl	5 g
Agar	15 g
Water	1 liter
pH 7.2

Sodium pyruvate	0.3 g
K ₂ HPO ₄	0.3 g
MgSO ₄	0.05 g
Bacto agar	15 g
Distilled water	1 liter
pH 7.2	

Identification

The unique composition of peptidoglycan with two diamino acids, DAB and ornithine, glutamate plus hydroxyglutamate, alanine and glycine is the most striking chemotaxonomic marker which differentiates *Agreia* from other genera of the family Microbacteriaceae (Table 1). *Agreia bicolorata* is characterized by yellow or orange pigmentation of colonies, becoming brown-orange or brown-red with age, irregular rods (0.4–0.5 × 1.5–2.5 µm), abundant polysaccharide capsule, predominant rhamnose and minor fucose and mannose in the cell wall, and the major menaquinone MK-10, with minor amounts of MK-9. Oxidase reaction with tetramethyl-*p*-phenylenediamine is positive, a wide range of carbohydrate and organic acids is used for the growth, H₂S is produced, and no growth occurs in media with 6% NaCl (Evtushenko et al., 2001). The species *Agreia pratensis* differs from *Agreia bicolorata* by yellow colonies, major menaquinones MK-10 and MK-11, negative oxidase reaction, and some physiological properties (Behrendt et al., 2002).

The Genus *Agrococcus*

The genus *Agrococcus* with the type species *Agrococcus jenensis* was established by Groth et al. (1996). Recently, two other species have been added to the genus (Wieser et al., 1999; Zlamala et al., 2002a).

Phylogeny

Representatives of the genus form a tight phylogenetic cluster with a 100% bootstrap confidence level, linked peripherally to the genus *Cryobacterium* (Suzuki et al., 1997; Fig. 1).

Taxonomy

The genus *Agrococcus* harbors coccoid, non-motile, non-acid-fast, microaerophilic, oxidase-negative bacteria. Their cell wall peptidoglycan contains DAB, alanine, glycine, aspartate, and glutamate; threonine may present in some species (Table 1). No mycolic acids are present. The major menaquinones are MK-11 and MK-12. Diphosphatidylglycerol and phosphatidylg-

lycerol are predominant polar lipids; two unknown glycolipids and some noncharacterized lipids were also detected. Polyamine pattern contains mainly spermine. The main whole-cell sugars glucose and rhamnose and minor amounts of mannose, ribose, galactose and tyvelose are typical for the species *Agrococcus jenensis* and *Agrococcus citreus*. The G+C content of DNA is 74 mol%. The strains grow at 37°C, with no growth at 42°C; they use a wide spectrum of carbon sources for growth and decompose some organic substrates. Usually they tolerate 4% NaCl but not 10% NaCl and are susceptible to many antibiotics but grow in the presence of 300 IU of polymyxin B and 200 µg of sulfonamide (Groth et al., 1996; Altenburger et al., 1996; Wieser et al., 1999; Zlamala et al., 2002a).

The current genus *Agrococcus* includes the following three species: *Agrococcus jenensis* (Groth et al., 1996), *Agrococcus citreus* (Wieser et al., 1999), and *Agrococcus baldri* (Zlamala et al., 2002a). The species differentiation is based on cell wall peptidoglycan composition, polar lipid pattern, fatty acid profile, and a number of physiological properties (Groth et al., 1996; Wieser et al., 1999; Zlamala et al., 2002a) as summarized in the subsection Identification in this Chapter.

Habitat

Little is known about the natural habitat of agrococci, as strains have been obtained from a variety of sources. Strains of *Agrococcus jenensis* were isolated from frozen compost soil in Jena, Germany, and a sandstone surface of the building Alte Pinakothek, Munich, Germany (Groth et al., 1996). Strains of *Agrococcus baldri* were recovered from air of the “Virgilkapelle” in Vienna, Austria (Zlamala et al., 2002a), while *Agrococcus citreus* was isolated from a medieval wall painting in the church of Herberstein castle in Styria, Austria (Wieser et al., 1999). Fritz (2000) found a representative of this genus, strain “*Corynebacterium* cf. *aquaticum*” V4.BO.26 (AJ244681), in the Mediterranean Sea at a depth of 600 m.

Isolation

The dilution plating technique has been applied on nutrient agar containing 2% peptone, PYES agar and some other media to isolate bacteria of the genus *Agrococcus* (Groth et al., 1996; Wieser et al., 1999). Cells of *Agrococcus baldri* were collected from the air using an air sampler and then grown on CasMM-agar (Altenburger et al., 1996) at room temperature (Zlamala et al., 2002a). Organisms of the genus grow well on a number of media, including tryptic soy agar,

PYES agar, CB agar and some others at appropriate temperature conditions, from 18 to 28°C.

Nutrient agar based on 2% peptone (Groth et al., 1996)

Peptone	20 g
Pancreatic digest (meat, fish)	5 g
NaCl	5 g
Agar	12 g
Distilled water	1 liter
pH 7.2–7.4	

PYES agar (Wieser et al., 1999)

Peptone	3 g
Yeast extract	3 g
Na ₂ -succinate	2.3 g
Agar	15 g
Distilled water	1 liter
pH 7.2	

CasMM-agar (Altenburger et al., 1996)

Casein	0.8 g
Yeast extract	0.4 g
K ₂ HPO ₄	0.6 g
Na ₂ HPO ₄ · 2H ₂ O	0.5 g
MgSO ₄ · 7H ₂ O	0.05 g
MgCl ₂ · 7H ₂ O	0.1 g
KNO ₃	0.2 g
FeCl ₃ · 6H ₂ O	0.01 g
Agar	15 g
Distilled water	1 liter
pH 7.0	

Identification

Agrococci can be easily distinguished from other Gram-positive coccoid bacteria by the amino acid composition of peptidoglycan. Spherical shape is the most striking feature that differenti-

ates the *Agrococcus* species from all other genera of the family Microbacteriaceae. Other associated characteristics differentiating the genus from other taxa of the family at the phenotypical level are given in Table 1.

Agrococcus jenensis is differentiated from *Agrococcus citreus* and *Agrococcus baldri* mainly by cell wall peptidoglycan composition and fatty acid profile (Zlamala et al., 2002a). The peptidoglycan of *Agrococcus jenensis* contains alanine, glycine, DAB, aspartate, glutamate and threonine in the molar ratio 3:2:0.7:1:1:1 (data for the type strain; Groth et al., 1996), while no threonine was determined in *Agrococcus citreus*; the molar ratio of alanine, glycine, aspartic and glutamic acids was 3.6:2.1:0.8:0.9:1 (Wieser et al., 1999). Similarly, no threonine was found in *Agrococcus baldri* (Zlamala et al., 2002a). *Agrococcus baldri* differs from the other two species by an unknown glycolipid not detected in *Agrococcus jenensis* or *Agrococcus citreus* (Zlamala et al., 2002a). Some physiological properties useful for discrimination of these three species are listed in Table 2.

The Genus *Agromyces*

Gledhill and Casida (1969) proposed the genus *Agromyces* with the type species *Agromyces ramosus* to accommodate filamentous, branching, fragmenting, nutritionally fastidious, catalase-negative soil isolates. Showing a negative oxidase reaction with benzidine and tetramethyl-*p*-phenylenediamine, the type strain of *Agromyces ramosus* produces cytochromes *b*, *c* and *aa*₃,

where aa_3 is the cytochrome oxidase (Jones et al., 1970). The strain was later characterized by a peptidoglycan of the B2 γ type (Schleifer and Kandler, 1972; Fiedler and Kandler, 1973a), a major menaquinone MK-12, predominant unsaturated *iso*- and *anteiso*-branched fatty acids, and the polar lipids diphosphatidylglycerol, phosphatidylglycerol, and a glycolipid (Collins, 1982a). In 1992, Zgurskaya et al. described 14 soil isolates that had the morphological and chemotaxonomic characteristics typical of the genus *Agromyces* but grew rapidly on simple media and showed positive catalase and oxidase reactions. The authors classified those into two new species and four subspecies, *Agromyces cerinus* subsp. *cerinus*, *Agromyces cerinus* subsp. *nitratus*, *Agromyces fucosus* subsp. *fucosus*, and *Agromyces fucosus* subsp. *hippuratus*, with emendation of the genus description (Zgurskaya et al., 1992). Later, Suzuki et al. (1996) found that the DNA-DNA relatedness between subspecies of *Agromyces fucosus* was 45–47%, lower than the level usually considered to be the border of genomic species (Wayne et al., 1987). Suzuki et al. (1996) described *Agromyces mediolanus*, which included the misclassified bacteria “*Corynebacterium mediolanum*” (Mamoli, 1939), “*Flavobacterium dehydrogenans*” (Arnaudi, 1942), and some soil isolates (Aoki et al., 1982), which do not usually produce mycelium. The genus has recently been enlarged by *Agromyces luteolus*, *Agromyces rhizosphaerae* and *Agromyces brachium* isolated from the mangrove rhizosphere (Takeuchi and Hatano, 2001), *Agromyces aurantiacus* found in a Chinese primeval forest soil (Li et al., 2003), and *Agromyces albus* isolated from a plant, *Androsace* sp. (Dorofeeva et al., 2003).

Phylogeny

On the basis of 16S rRNA gene sequencing studies, organisms of *Agromyces* form a phylogenetically coherent group that is clearly distinct from other genera of Microbacteriaceae (Fig. 1).

Taxonomy

The genus *Agromyces* currently harbors nine species and two subspecies:

Agromyces ramosus (Gledhill and Casida, 1969), *Agromyces albus* (Dorofeeva et al., 2003), *Agromyces aurantiacus* (Li et al., 2003), *Agromyces brachium* (Takeuchi et al., 2001), *Agromyces cerinus* subsp. *cerinus*, *Agromyces cerinus* subsp. *nitratus*, *Agromyces fucosus* subsp. *fucosus* and *Agromyces fucosus* subsp. *hippuratus* (Zgurskaya et al., 1992), *Agromyces luteolus*, *Agromyces rhizosphaerae* (Takeuchi et al., 2001), and *Agromyces mediolanus* (Suzuki et al., 1996).

Members of the genus are characterized by opaque, paste, entire colonies, usually penetrating into agar. Branching hyphae (width, 0.2–0.8 μ m) break up into diphtheroid and rodlike, irregular, nonmotile fragments. Nonmycelial strains occur. No aerial mycelium and spore formation are usually observed, except for *A. aurantiacus* which forms aerial mycelium on glycerol-asparagine agar (Li et al., 2003). Cells are aerobic to microaerophilic. Catalase test and oxidase reaction with tetramethyl-*p*-phenylenediamine are variable for different species. Mesophilic, optimal growth occurs at 24–30°C, and some strains grow at 37°C. Strains utilize a wide range of C and N sources and grow on media containing organic or inorganic nitrogen. The peptidoglycan is of the B2 γ type (Schleifer and Kandler, 1972) based upon DAB (mostly L-isomer; Sasaki et al., 1998) and contains amino acids glycine, glutamate, DAB and alanine in a molar ratio close to 1:1:2:1. Galactose and rhamnose occur in the cell wall of most strains; fucose, fructose, glucose, mannose, ribose and tyvelose vary in different species. No mycolic acids are found. The predominant menaquinone is MK-12, and the second most common component is MK-11 or MK-13, depending on the species. Polar lipids are represented by diphosphatidylglycerol, phosphatidylglycerol and glycolipids; *iso*- and *anteiso*-branching fatty acids are predominant and can reach 94% (Zgurskaya et al., 1992; Suzuki et al., 1996; Takeuchi et al., 2001). Cell wall teichoic acids and related anionic polymers were found in some species and subspecies (Naumova et al., 2001). The total polyamine content in some of the *Agromyces* species investigated is lower than that in most other strains of the family Microbacteriaceae and consists of only 0.21–0.28 μ mol·g⁻¹, with putrescine as a predominant component (Altenburger et al., 1997).

The species and subspecies differentiation is based on growth, morphological, chemotaxonomic and physiological characteristics as outlined in the subsection Identification in this Chapter.

Habitat

The usual natural habitat of agromycetes is soil of different origin (Gledhill and Casida, 1969; Zgurskaya et al., 1992; Suzuki et al., 1996; Takeuchi and Hatano, 1999; Takeuchi and Hatano, 2001; Li et al., 2003). *Agromyces ramosus* has been reported to be the numerically prevalent organism in soil (Gledhill and Casida, 1969). *Agromyces luteolus*, *Agromyces rhizosphaerae* and *Agromyces brachium* (Takeuchi and Hatano, 2001), along with many kinds of other actinomycetes, were isolated from the rhizosphere of *Bruguiera gymnorhiza* (L.) Savigny

and *Sonneratia alba* Sm. in the subtropical and tropical regions of Okinawa, Japan (Hatano, 1997; Takeuchi and Hatano, 1999). Strain *Agromyces mediolanus* ATCC 13990 (the former "*Flavobacterium dehydrogenans*") was recovered from pressed yeast cake (Arnaudi, 1942; Cummins et al., 1974), and *Agromyces albus* was isolated from the above-ground part of a plant *Androsace* sp. (the family Primulaceae), Belgorod region, Russia (Dorofeeva et al., 2003). The microorganisms of the genus were also found in the stalactites, Grotta dei Cervi, Porto Badisco, Italy (Laiz et al., 2000); in more than 500,000-year-old glacial ice, Guliya, China (Christner, 2002); a medieval wall painting (Altenburger et al., 1996); skin and muscle of the Tyrolean iceman (Rollo et al., 2000), and some other sources. Organisms phylogenetically related to *Agromyces* were revealed in casts of the earthworm *Lumbricus rubellus* (Furlong et al., 2002), and a strain tentatively identified as *Agromyces* sp. was isolated from a site highly contaminated with chloroaromatic compounds, although the strain was not capable of trichlorophenol degradation (Maltseva and Oriel, 1996).

Isolation

Many nutrient media, e.g., diluted (1:10) CB agar (Zgurskaya et al., 1992), R agar (Yamada and Komagata, 1972a), AR2 agar (Difco), and some others are suitable for isolation of the fast-growing aerobic species of the genus *Agromyces*. Among other bacteria developing on nutrient agar media, most *Agromyces* strains can preliminarily be recognized owing to their pale-yellow or yellow paste colonies penetrating into agar media. *Agromyces ramosus* is often difficult to isolate because of problems providing the appropriate growth conditions. This species is likely microaerophilic because it lacks catalase and grows best under full oxygen tension, provided that accumulation of H_2O_2 is avoided. Removal of H_2O_2 can be achieved by the addition of catalase, fresh horse blood, or MnO (Jones et al., 1970). *Agromyces ramosus* may be isolated from soil using the dilution frequency procedure described in detail by Casida (1965). The approach is based on the fact that *Agromyces ramosus* occurs in high quantities in many soils. In soils, where *Agromyces ramosus* is not predominant, *Actinomyces humiferus* may be recovered instead of *Agromyces ramosus* (Gledhill and Casida, 1969). *Agromyces ramosus* grows very slowly during the first transfers and might be lost easily. Once adapted, usually growth is without problems on nutritionally rich media. Heart infusion agar at 30°C is a suitable medium for growth (Gledhill and Casida, 1969).

Heart Infusion Agar (Gledhill and Casida, 1969)

Heart infusion broth (Difco)	25 g
Bacto yeast extract (Difco)	5 g
Casitone (Difco)	4 g
Agar	15 g
Distilled water	1 liter

Bacto yeast extract (Difco)	5 g
Bacto malt extract (Difco)	5 g
Bacto casamino acids (Difco)	5 g
Bacto beef extract (Difco)	2 g
Glycerol	2 g
Tween 80	50 mg
MgSO ₄ · 7H ₂ O	1 g
Agar	20 g
Distilled water	1 liter
pH 7.2	

Identification

Novel isolates can be readily identified as members of the genus *Agromyces* by 16S rRNA gene sequence analysis. Most strains can also be referred to the genus by the presence of DAB in the cell wall and a branched fragmenting mycelium (Table 1). Only *Agromyces mediolanus* does not usually produce a mycelium (Suzuki et al., 1996). This species differs from most other DAB-containing genera by the predominant menaquinone MK-12 and nonmotile rod-shaped cells. The major menaquinone MK-12, typical for *Agromyces* species, is also found in members of *Agrococcus* and, together with the second predominant component MK-11, in some species of *Leifsonia* (which are characterized by clearly motile cells; Table 1). In addition, *Agromyces* spp. exclusively possess L-DAB in the peptidoglycan, while *Leifsonia* spp. contain both L- and D- isomers in almost equal proportion (Sasaki et al., 1998). The species and subspecies of the genus *Agromyces* differ from each other in colony color, cell morphology, cell wall sugars, the complex media requirement for growth, the oxidase test with tetramethyl-*p*-phenylenediamine, and some other physiological characteristics (Table 3).

Applications and Properties

Agromyces ramosus ATCC 25173 and several strains assigned to "*Agromyces okinawai*" produced a highly thermally stable immunostimulant with antitumor, antiviral, interferon-inducing and immunity response-potentiating activities (Wakuzaka et al., 1983). Immunoactivating properties were also found for the cell wall polymers of *Agromyces cerinus* (H. I.

Data from Gledhill and Casida (1969), Zgurskaya et al. (1992), Suzuki et al. (1996), Takeuchi and Hatano (2001), Dorofeeva et al. (2003), and Li et al. (2003).

Zgurskaya and L. I. Evtushenko, unpublished observation). Production of 3,6-dideoxy-D-arabinose (tyvelose) was patented for *Agromyces cerinus* subsp. *cerinus* strain (Zgurskaya and Evtushenko, 1996). Production of D-N-carbamyl- α -amino acids, e.g., D-N-carbamylalanine, by conversion of 5-substituted hydantoin using immobilized *Agromyces* sp. has been reported; the compounds are useful for the production of pharmaceuticals and agrochemicals (Mitsubishi Kaseo Corporation, 1989). An experimental biofilter containing tree bark compost was used to treat raw gas emissions (aldehyde, ketone, furan, thiophene and alkylsulfide compounds, hydrogen sulfide, ammonia and CO₂) from animal rendering. Two strains of *Agromyces*, along with *Corynebacterium* and *Gordonia* strains, were reported among the bacteria present in the biofilter used for waste-gas treatment of an animal rendering plant and pollutant degradation (Bendinger et al., 1990). Some *Agromyces mediolanus* strains assimilate aniline (Aoki et al., 1982; Suzuki et al., 1996). *Agromyces mediolanus* ATCC 14004 and *Agromyces mediolanus* ATCC 13930 are capable of oxidizing steroids (Mamoli, 1939; Arnaudi, 1942), and *Agromyces mediolanus* ATCC 13930 can be used for a microbiological process for the preparation of oxoalkylxanthines (Nesemann et al., 1974). *Agromyces ramosus*, strains ATCC 25173 and PSU 35, attack and destroy cells of *Saccharomyces cerevisiae* and several bacteria, including *Agrobacterium tumefaciens*, *Rhizobium leguminosarum*, *Sinorhizobium meliloti* (formerly, *Rhizobium meliloti*), *Staphylococcus aureus*, *Escherichia coli* and *Pseudomonas fluorescens*. The strains may be manipulated to control levels of *Agrobacterium tumefaciens* and other pathogens without simultaneously depressing the numbers of beneficial organisms in this habitat (Casida, 1983).

Agromyces ramosus was reported to produce the L-form which reverted to a bacterial form when incubated in sterilized soil or in some suitable culture media (Horwitz and Casida, 1978a; Horwitz and Casida, 1978b). Pure cultures of this species can also produce small cells caused by growth on nutritionally limiting agar media (Casida, 1977). *Agromyces ramosus* showed slight activity in oxidizing CO to CO₂; the reaction was proposed to be caused by microbial activity because an appreciable amount of CO was not converted to CO₂ in autoclaved or γ -irradiated soil (Bartholomew and Alexander, 1979). In *Agromyces cerinus* subsp. *cerinus* VKM Ac-1340, a new unusual structure of teichoic acid with arabitol in the main chain was identified (Shashkov et al., 1995). A new polymer of 1,5-poly(ribitol phosphate) with tetrasaccharide substituents was revealed in the cell wall of

Agromyces fucosus subsp. *hippuratus* (Gnilozub et al., 1994).

The Genus *Clavibacter*

The genus *Clavibacter* was established by Davis et al. (1984b) to accommodate several plant pathogenic species and subspecies. These organisms, which were formerly attributed to a separate group of plant pathogens in the genus *Corynebacterium* (Collins and Bradbury, 1986), contain DAB in the cell wall peptidoglycan (type B2 γ ; Schleifer and Kandler, 1972) and unsaturated menaquinones (Collins and Jones, 1980a). The current genus *Clavibacter* (including one species *Clavibacter michiganensis* with five subspecies) is restricted only by presence of the major menaquinone MK-9, the B2 γ type peptidoglycan, and some associated properties (Davis et al., 1984b).

The type strain *Clavibacter michiganensis* subsp. *michiganensis* NCPPB 2581^T (CIP 104846^T, DSM 46364^T, ICMP 2550^T, JCM 9665^T, LMG 7333), originally described as "*Bacterium michiganense*" (Smith, 1910), was the first documented living bacterium of the genus *Clavibacter sensu stricto*. Later, members of *Clavibacter michiganensis* subsp. *sepedonicus* and *Clavibacter michiganensis* subsp. *insidiosus* originally assigned to the species "*Bacterium sepedonicum*" (Spieckermann and Kotthoff, 1914) and "*Aplanobacter insidiosus*" (McCulloch, 1925) were reported. Following reclassification, the bacteria were allocated to the genus *Corynebacterium* as the separate species *Corynebacterium michiganense*, *Corynebacterium insidiosum* and *Corynebacterium sepedonicum* (Cummins et al., 1974). After half a century, another plant pathogenic species, *Corynebacterium nebraskensis*, was described (Vidaver and Mandel, 1974).

Carlson and Vidaver (1982), who revealed almost identical cellular protein patterns of these organisms and novel strains causing wheat disease, proposed to combine *Corynebacterium michiganense*, *Corynebacterium insidiosum*, *Corynebacterium nebraskense* and *Corynebacterium sepedonicum* into a single species, *Corynebacterium michiganense*. This was consistent with the previous conclusion of Dye and Kemp (1977), based on a high phenotypic similarity of these species. In contrast to Dye and Kemp, who considered the bacteria as pathovars of *Corynebacterium michiganense*, Carlson and Vidaver reclassified them as subspecies, with description of a new subspecies associated with wheat, *Corynebacterium michiganense* subsp. *tessellarium*. The authors noted that the bacterial differences on the basis of colony morphology and

pigmentation, overall bacteriocin production (Gross and Vidaver, 1979b), some biochemical reactions, and menaquinone pattern are independent of pathogenic specificity (Carlson and Vidaver, 1982). They also commented on the inappropriateness of the term “pathovar” for avirulent strains and that designation of these organisms as subspecies would allow the rational identification of related saprophytes and avirulent strains. The proposed names were validated as *Corynebacterium michiganense* subsp. *michiganense* (Smith, 1910) Jensen 1934, *Corynebacterium michiganense* subsp. *insidiosum* (McCulloch, 1925) Carlson and Vidaver 1982, *Corynebacterium michiganense* subsp. *nebraskense* (Vidaver and Mandel, 1974) Carlson and Vidaver 1982, *Corynebacterium michiganense* subsp. *sepedonicum* (Spieckermann and Kotthoff, 1914) Carlson and Vidaver 1982, and *Corynebacterium michiganense* subsp. *tessellarium* Carlson and Vidaver 1982.

Unaware of the description of the genus *Clavibacter* and five subspecies of *Clavibacter michiganensis* (Davis et al., 1984b), Collins and Bradbury (1986), summarizing information on DNA-DNA reassociation (Starr et al., 1975; Döpfer et al., 1982), serological specificity (Lazar, 1968), differences in cellular proteins (Carlson and Vidaver, 1982), lipids (Minnikin et al., 1978; Collins and Jones, 1980a), biochemical and physiological features (Jones, 1975; Dye and Kemp, 1977) and some other data, concluded that four subspecies of *Corynebacterium michiganense* (*michiganense*, *insidiosum*, *nebraskense* and *sepedonicum*) warrant a separate species status. Although Collins and Bradbury stated that none of these organisms belonged to the genus *Corynebacterium sensu stricto*, they retained the generic name *Corynebacterium* for the purpose of convenience and practicability. With additional data on the differences of the subspecies in allozyme pattern (Riley et al., 1988) and fatty acid composition (Henningson and Gudmestad, 1991) and the results of numerical, chemotaxonomic and DNA-DNA relatedness studies of a large set of plant pathogenic and saprophytic clavibacteria, Zgurskaya (1993a) provided additional evidences that the *Clavibacter michiganensis* subspecies are actually separate species as concluded by Collins and Bradbury (1986). Furthermore, some saprophytic and environmental clavibacteria were found to probably represent novel species of the genus (Zgurskaya, 1993a; Dobrovolskaya et al., 1999; Nazina et al., 2002).

The situation outlined shows that the intrageneric structure of the genus *Clavibacter* needs to be revised in the future, in that the subspecies of *Clavibacter michiganensis* needs to be reclassified as a species.

Phylogeny

Clavibacteria form a tight cluster within the Microbacteriaceae phylogenetic branch and are close to the genus *Frigoribacterium* (Kämpfer et al., 2000), showing up to 97% 16S rDNA sequence similarity to this genus (Fig. 1).

Taxonomy

Currently, the genus *Clavibacter* includes one species, *Clavibacter michiganensis*, with five subspecies (Davis et al., 1984b): *Clavibacter michiganensis* subsp. *michiganensis* (Smith, 1910), *Clavibacter michiganensis* subsp. *insidiosum* (McCulloch, 1925), *Clavibacter michiganensis* subsp. *nebraskensis* (Vidaver and Mandel, 1974), *Clavibacter michiganensis* subsp. *sepedonicus* (Spieckermann and Kotthoff, 1914), and *Clavibacter michiganensis* subsp. *tessellarius* (Carlson and Vidaver, 1982).

Members of the genus *Clavibacter* are characterized by nonsporeforming, nonmotile, irregular rods (ca. 0.5–0.7 × 0.75–1.5 µm), which occur singly or in pairs with diphtheroid arrangements. Primary branching is not observed. Cells are aerobic, catalase positive, and usually show a negative or weakly positive oxidase reaction with tetramethyl-*p*-phenylenediamine. Thermal optimum is about 25–28°C. The peptidoglycan type is B2γ [L-DAB] D-glu-D-DAB (Schleifer and Kandler, 1972; Sasaki et al., 1998). Cell wall sugars are represented by rhamnose, galactose and mannose; glucose and fucose also occur in some strains (Davis et al., 1984b; Zgurskaya et al., 1993b). Mycolic acids are not present. The major menaquinone is MK-9; menaquinones MK-7, MK-8 and MK-10 may be detected as minor components. Principal phospholipids are phosphatidylglycerol and diphosphatidylglycerol; three unknown glycolipids are present. Saturated *anteiso*-branched fatty acids *ai*-17:0 and *ai*-15:0 are predominant (Collins and Jones, 1980a; Sasaki et al., 1998). The G+C content of DNA is 69–78 mol% (Yamada and Komagata, 1970; Döpfer et al., 1982). Discrimination of subspecies is based on cultural features, physiological characteristics, and cell wall sugars (see subsection Identification in this Chapter), which are consistent with their grouping on the basis of DNA-DNA relatedness (Döpfer et al., 1982; Zgurskaya, 1993a) and their plant hosts (Vidaver, 1982).

Habitat and Phytopathogenicity

Published data suggest that bacteria of the genus *Clavibacter* are usually associated with different diseased or healthy plants and related sources (Cummins et al., 1974; Vidaver, 1982; Collins and

Bradbury, 1992; Zgurskaya, 1993a; Dobrovolskaya et al., 1999; Sundin and Jacobs, 1999; Behrendt et al., 2002; Zinniel et al., 2002). They can also occur in soil and other environments, including oil fields, glacial and subglacial environments, and a deep subsurface paleosol (Hou et al., 1997; Chandler et al., 1998; Christner, 2002; Nazina et al., 2002).

OCCURRENCE OF PLANT-ASSOCIATED SAPROPHYTIC CLAVIBACTERIA Saprophytic clavibacteria inhabit different plants and related sources worldwide. Along with representatives of *Curtobacterium* and Gram-negative bacteria, they constitute a significant proportion in the microbial communities of grass phyllosphere decaying surface litter after mulching the sward (Behrendt et al., 1997; Behrendt et al., 2002). Numerous clavibacteria, including rose-pigmented strains, were isolated from different plants (*Ammodendron* sp., *Bromus* sp., *Collidonium* sp., *Ephedra* sp., *Gagea* sp., *Salsola* sp., etc.) and related sources collected in desert areas of Middle Asia (Zgurskaya, 1993a; Dobrovolskaya et al., 1999). The pigmented clavibacteria and curtobacteria predominated among highly ultraviolet (UV)-tolerant strains revealed in the phyllosphere of the field-grown peanut, *Arachis hypogaeae* L., Texas, United States (Sundin and Jacobs, 1999; Jacobs and Sundin, 2001). Recent data provide evidence that clavibacteria can exist as endophytes (Kado, 1992) living in plant tissues of several agronomic crops without doing substantial harm (Zinniel et al., 2002). However, still little is known about the role of epiphytic and endophytic clavibacteria in the life of the plant. Other endophytic bacteria have been associated with the growth promotion of plants (for the references, see Hallmann et al., 1997). The beneficial effects of bacterial endophytes vary but appear to operate through similar mechanisms (Kloepper et al., 1991). They also may contribute to the control of bacterial and fungal pathogens (Hallmann et al., 1997; Reiter, et al., 2002) and also of plant parasitic nematodes (Hallmann et al., 1997) and insects (Dimock et al., 1988). Several strains of unidentified *Clavibacter* sp. were isolated from seed galls induced by plant parasitic nematode *Anguina agrostis* on *Agrostis* sp. However, clavibacteria were not predominant among other coryneform isolates in bacterium-nematode complexes in the galls and most likely are secondary settlers of the galls, descending from the phyllosphere or healthy plant tissue (L. I. Evtushenko et al., unpublished observation).

PLANT PATHOGENIC *CLAVIBACTER MICHIGANENSIS*

Plant Hosts The main habitats of plant pathogenic *Clavibacter michiganensis* subspecies are

considered to be the respective host plants. In nature, each pathogen has been found in one or a few usually related genera of plants (Bradbury, 1986). *Clavibacter michiganensis* subsp. *insidiosus* occurs in lucerne (alfalfa; *Medicago sativa* L.) and a few other pasture legumes (*Trifolium* spp., *Melilotus albus* Medic., *Onobrychis viciifolia* Scop. [syn. *Onobrychis sativa* L.], and *Lotus corniculatus* L.). *Clavibacter michiganensis* subsp. *nebraskensis* is associated with corn (*Zea mays* L.). *Clavibacter michiganensis* subsp. *sepedonicus* inhabits diseased potatoes (*Solanum tuberosum* L.). *Clavibacter michiganensis* subsp. *tessellarius* occurs on wheat (*Triticum aestivum* L.). *Clavibacter michiganensis* subsp. *michiganensis* is limited to solanaceous hosts, principally tomato (*Lycopersicon esculentum* Mill.) and pepper (*Capsicum annuum* L.), but was also revealed in the diseased solanaceous weeds, *Solanum nigrum* L., *Solanum triflorum* Nutt. and *Lycopersicon pimpinellifolium* (L.) Mill. (syn. *Solanum pimpinellifolium* L.) (Vidaver, 1982; Collins and Bradbury, 1986; Vidaver and Davis, 1988). The subspecies *michiganensis*, *sepedonicus* and *insidiosus* were reported to infect some other plants related to their host plants when inoculated (Collins and Bradbury, 1986).

Vascular Diseases Caused by *Clavibacter* and Disease Symptoms *Clavibacter michiganensis* with its five subspecies causes a vascular disease with very high titers in a variety of agriculturally important plants and, in fact, may be considered the most important bacterial pathogen (Jahr et al., 1999). The subspecies *sepedonicus* and *michiganensis* are subject to international quarantine regulations (European Union, 1995; Li and De Boer, 1995b). Infection of the host plant usually occurs via wounds, followed by invasion of the xylem vessels, which establishes a systemic vascular disease (Wallis, 1977). After some time, the plants develop wilt and other symptoms and may perish. *Clavibacter michiganensis* subsp. *michiganensis* causes wilt, fruit spot and canker in solanaceous hosts, principally tomato and pepper. The subspecies *insidiosus* causes wilting and stunting in lucerne and a few other pasture legumes. The subspecies *nebraskensis* induces wilt, leaf blight and spot in corn, the subspecies *sepedonicus* is a casuative agent of wilt and tuber rot in potato, while the subspecies *tessellarius* induces a mosaic-like syndrome on wheat (Vidaver, 1982; Vidaver and Davis, 1988). Symptoms of these various hosts, which are often slow to develop, include also decreased vigor, stunting, leaf yellowing and leaf spot, stem or tuber necrosis. Wilt is commonly seen as an early symptom only with *Clavibacter michiganensis* subsp. *michiganensis* infections (Van Alfen,

1989). Environmental factors sometimes crucially affect disease development. Temperature, humidity and pollution can have both synergetic and antagonistic effects on symptom expression (Vidaver, 1982).

An infection at a late stage of plant development resulting in a latent infection is also destructive, as contaminated seeds or, in the case of potato, infected tubers or stems are produced that spread the disease (Nelson, 1982; Jahr et al., 1999).

Pathogenicity Factors Originally, extracellular polysaccharides (EPS) were proposed to be the main pathogenicity factor inducing wilt symptoms by interfering with water transport (for the references, see Vidaver [1982] and Denny [1995]). Strobel and Hess (1968) argued that a mechanism other than plugging exists which causes wilting by the toxic extracellular “glycopeptide” from *Clavibacter michiganensis* subsp. *sepedonicus*. The authors demonstrated that wilt was induced by ultrastructural membrane and cell wall damage rather than interference with water transport. This idea was no longer considered valid, as other workers could not confirm the results (see Vidaver [1982], Van Alfen [1989], and Denny [1995]). However, the toxic “glycopeptides” described by Strobel and Hess (1968) and some others are actually polysaccharide(s) closely associated with polypeptide, and different authors used EPS material of different quality (Denny, 1995). There is no reliable physiological and histological evidence that adequately purified polysaccharides rapidly affect plant membranes during the early stages of pathogenesis (Van Alfen, 1989; Benhamou, 1991; Denny, 1995). Furthermore, Bermpohl et al. (1996), who studied the EPS⁻ mutants of *Clavibacter michiganensis* subsp. *michiganensis* producing only 10% of the amount of EPS of the wildtype, showed that virulence did not change in mutants tested on tomato plants. Paschke and Van Alfen (1993), studying UV-mutants of *Clavibacter michiganensis* subsp. *insidiosus* lacking EPS, also concluded that it was unlikely that EPS of this plant pathogen played an important role in the early stages of disease establishment.

Histological and genetic studies of *Clavibacter michiganensis* suggested that plant cell-wall degrading enzymes contribute to main disease symptoms (Wallis, 1977; Vidaver, 1982; Benhamou, 1991; Meletzus et al., 1993; Jahr et al., 1999). Jahr et al. (2000) presented clear evidence that the 78-kDa CelA protein (746 amino acids) with similarity to endo- β -1,4-glucanases of family A1 cellulases (which is encoded by plasmid pCM1; Meletzus et al., 1993) plays a major role in pathogenicity of

Clavibacter michiganensis subsp. *michiganensis*. Wilt-inducing capability was obtained by endoglucanase expression in plasmid-free, avirulent strains and by complementation of the *celA*-gene-replacement mutant CMM-H4 with the wildtype *celA* gene. Some evidence was obtained that endocellulase is insufficient itself for expression of a virulent phenotype in the tomato test system. It obviously requires an additional gene product, also encoded by plasmid pCM1, which remains to be identified (Jahr et al., 1999). Another pathogenic determinant of *Clavibacter michiganensis* subsp. *michiganensis* is encoded by *pat-1* gene (1500 nucleotides) located on the second plasmid, pCM2 (72 kb). According to sequence homologies, the product of this gene is somewhat homologous to serine proteases from *Lyso-bacter enzymogenes* and *Streptomyces griseus* (Dreier et al., 1997). In addition, the pathogenic *Clavibacter michiganensis* subsp. *michiganensis* strains were reported to induce a hypersensitive reaction on certain non-host or resistant plants, which is a fast response at the site of pathogen invasion, characterized by a rapid, localized plant cell death (Gitaitis, 1990; Bermpohl et al., 1996; Dangl et al., 1996; Alarcon et al., 1998). The hypersensitivity was also induced when the protein(s) from the culture supernatant of *Clavibacter michiganensis* subsp. *michiganensis* strain 623 is injected into leaves of non-host plants, four-o'clock (*Mirabilis jalapa*) and tobacco (*Nicotiana tabacum*). The properties observed for the necrosis-inducing activity resembled those of harpin and PopA proteins from Gram-negative phytopathogenic bacteria that elicit plant hypersensitive reactions (Alarcon et al., 1998).

Clavibacter michiganensis subsp. *sepedonicus* also produces cellulase (Baer and Gudmestad, 1995), which was shown to play a role in virulence (Metzler et al., 1997; Laine et al., 2000). A cellulase-free mutant as well as a naturally occurring strain that does not contain the pCS1 plasmid was shown to have a markedly reduced virulence on eggplant. Both strains became significantly more virulent after the cellulase gene was introduced into the cells by transformation. The complete nucleotide sequence of the cellulase gene was determined and shown to encode a protein of 727 amino acids with molecular weight of 71.5 kDa. The sequence included a leader sequence for secretion and showed two typical cellulase domains (a catalytic domain and a cellulose binding domain). In addition, the authors identified an unexpected third domain that shows similarity to a plant protein called “expansin,” which was believed to interact with cellulose microfibrils during plant cell expansion (Laine et al., 2000). *Clavibacter michiganensis*

subsp. *sepedonicus* was also found to produce amylase, which had an effect on virulence, although its effect was less important than that of cellulase. This enzyme probably plays an important role in the rotting of starchy potato tubers (Jahr et al., 1999). The wilting material from this species was also reported to contain 10–30% of nucleic acids, which were inactivated by DNase and RNase in combination (Pearson, 1971; Vidaver, 1982). *Clavibacter michiganensis* subsp. *sepedonicus* elicits a hypersensitive reaction on tobacco, secreting heat stable hypersensitive response-inducing protein(s) (Nissinen et al., 1997).

Southern hybridization experiments revealed that three other subspecies, *Clavibacter michiganensis* subsp. *insidiosus*, *Clavibacter michiganensis* subsp. *tessellarius*, and *Clavibacter michiganensis* subsp. *nebraskensis*, contain sequences hybridizing to the cellulase gene from *Clavibacter michiganensis* subsp. *michiganensis* (Dreier et al., 1995). *Clavibacter michiganensis* subsp. *nebraskensis* was also reported to secrete an anion channel-forming protein (Schurholz et al., 1991). The properties of this voltage-dependent chloride channel protein have only been studied *in vitro*, and the role of this component in disease development remains unclear (Jahr et al., 1999).

The Role of Extracellular Polysaccharides (EPS) Two distinct polymer types represent EPS of *Clavibacter michiganensis* subsp. *michiganensis*, *Clavibacter michiganensis* subsp. *insidiosus* and *Clavibacter michiganensis* subsp. *sepedonicus*. One of them is a low-molecular-weight neutral polymer, and the second is a generally high-molecular-weight acidic polymer that consists of fucose, galactose and glucose, decorated with acetate and pyruvate side groups, or additional mannose (*Clavibacter michiganensis* subsp. *sepedonicus*; for references, see Denny, 1995). It is now clear that EPS of *Clavibacter michiganensis* do not play an important role in the early stages of disease. However, EPS determine multiple and important biological functions and may affect pathogenicity, interfering with water transport. Acid EPS can act as ion exchangers, concentrating minerals and nutrients as well as binding toxic compounds. EPS may also prevent recognition of the pathogen by the plant defense system, block agglutinins or lectins and detoxify phytoalexins or reactive oxygen species (Bradshaw-Rouse et al., 1981; Romeiro et al., 1981; Young and Sequeira, 1986; Kiraly et al., 1997). In addition, EPS mediate adhesion to abiotic and biological surfaces and may also promote infection and colonization of the host plant, a prerequisite for disease development (Melet-

zus et al., 1993; Bermpohl et al., 1996; Saile et al., 1997). Variations in the sugar composition of EPS in *Clavibacter michiganensis* subsp. *michiganensis* were shown to correlate to the inability to colonize tomato plants, indicating that the chemical structure of EPS may play a role in host recognition and the early stages of infection (Bermpohl et al., 1996).

Survival, Sources of Inoculum, and Spreading

Plant pathogenic clavibacteria are considered to be poor survivors in soil; survival requires association with diseased plants, residue materials or seeds (Richardson, 1979; Richardson, 1983; Vidaver, 1982; Tsiantos, 1987; Nemeth et al., 1991). However, some bacteria were reported to survive in water for weeks (*Clavibacter michiganensis* subsp. *nebraskensis*) or more than a year (*Clavibacter michiganensis* subsp. *michiganensis*); the survival rate increased with cell concentration and with lowered temperatures (Vidaver, 1977; Vidaver, 1982; Tsiantos, 1986). *Clavibacter michiganensis* subsp. *sepedonicus* can survive for long periods on farm machinery, bins, sacks, kraft paper, and polyethylene plastic (Richardson, 1957; Nelson, 1980) and also in potatoes and sugar beets without causing symptoms (Hayward, 1974; Bugbee et al., 1987). Infectious bacteria can be recovered from dried potato stems of infected plants for 26 months and, in case of cv. Russet Burbank, over 5 years (Nelson, 1979; Nelson, 1985). Dried slime from symptomatic tubers especially favors long-term maintenance of the bacterium on surfaces. Freezing temperatures, rather than being deleterious to the bacterium, actually appear to enhance persistence (Slack, 1978; Nelson, 1980). It is suggested that plant pathogenic clavibacteria may spread from plant to plant through all the above sources (Vidaver, 1982). They may also be transmitted by rain, wind, or insects, as occurs for other bacteria inhabiting plants (Lindemann and Upper, 1985; Hirano et al., 1996; Lilley et al., 1997). Hawn (1963) reported that the root-knot nematode, *Ditylenchus dipsaci*, increased the frequency and severity of the bacterial wilt of lucerne caused by *Clavibacter michiganensis* subsp. *insidiosus*.

Isolation

ISOLATION OF PLANT PATHOGENIC CLAVIBACTERIA

Sources and Methods Plant pathogenic subspecies of *Clavibacter michiganensis* can be isolated from both infected and infested plants, particularly if the material is obtained from areas of known infection (Vidaver, 1982). The choice of a

suitable piece of tissue is of prime importance to avoid contamination with faster-growing bacteria. Material should be washed with tap water and gently blotted dry with paper toweling. Surface sterilization is usually unnecessary. The tissue should be carefully excised with sterile instruments. Young lesion material, freshly infected material, or the margins of decayed areas should be sought. Direct puncture from fresh tissue by use of a sharp, sterilized dissecting needle onto agar should be successful, as should streaking or plating of comminuted tissues after serial dilution (Vidaver and Davis, 1988). In a wilting plant, the vascular tissue near the base of the wilting sections will increase the recovery rate. The cut tissue is placed into sterile water to release bacteria. Discolorization at the cut vessels is a good indication of releasing. In case of stunting and chlorosis in lucerne or of mosaic in wheat, a vascular infection may occur and recovery of *Clavibacter michiganensis* subsp. *insidiosus* and *Clavibacter michiganensis* subsp. *tessellarius* can be anticipated. In case of cankers and necrotic lesions, the bacteria may be isolated from the moist or dull greasy tissue at the edge of unhealthy tissue. Old necrotic areas, rotten parts, or parts showing advanced stages of disease contain many saprophytes which may overgrow the *Clavibacter* cells, hampering or making impossible direct isolation from such material (Collins and Bradbury, 1992). *Clavibacter michiganensis* subsp. *sepedonicus* is often difficult to isolate from potato tubers because of the presence of many other microorganisms (Vidaver and Davis, 1988).

Isolation Media Primary isolation of plant pathogenic clavibacteria using dilution plating on a suitable selective or nonselective agar media is used to obtain presumptive information on the numbers of different bacteria. Sometimes this method results in the isolation of unexpected or new pathogens (Collins and Bradbury, 1992). Nutrient agar supplemented with 1% glucose or 5% sucrose (Lelliott and Stead, 1987), glucose-yeast-calcium (GYCA) medium (Moffett et al., 1983), NBY medium (Vidaver and Davis, 1988), Doppel's medium (Lelliott and Stead, 1987), CB agar or any other media based on peptone, yeast extract, and glucose may be used as nonselective media for isolation of plant pathogenic clavibacteria.

GYCA Medium (Moffett et al., 1983)

Glucose	5 g
Yeast extract	5 g
Finely ground CaCO ₂	41 g
Agar	15 g
Water	1 liter
pH 7.2	

Doppel's Medium (Lelliott and Stead, 1987)

Glucose	10 g
Yeast extract	8 g
Casein hydrolysate (not vitamin free)	8 g
K ₂ HPO ₄	2 g
MgSO ₄ · 7H ₂ O	0.3 g
Agar	12 g
Water	1 liter
pH 7.2	

NBY Medium (Gross and Vidaver, 1979a; Vidaver and Davis, 1988)

Nutrient broth	8 g
Yeast extract	2 g
K ₂ HPO ₄	2 g
KH ₂ PO ₄	0.5 g
Agar	15 g
Water	1 liter
pH 7.2	

Fifty ml of 50% glucose and 1.0 ml of 1M MgSO₄ · 7H₂O are both added after separate filter sterilization.

CNS medium enhances the chance of selectively recovering *Clavibacter michiganensis* subsp. *nebraskensis*, *Clavibacter michiganensis* subsp. *michiganensis* and *Clavibacter michiganensis* subsp. *tessellarius* (Gross and Vidaver, 1979a). The CNS medium is based on NBY medium which is supplemented with 1% lithium chloride and the following antibiotics: nalidixic acid, 25 mg (2.5 ml of freshly made 1% solution in 0.1M NaOH); polymyxin B sulfate, 32 mg (3.2 ml of a 1% aqueous solution of 8,000 USP units/mg, or a total of 256,000 units); cycloheximide, 40 mg (4 ml of 1% aqueous solution); and tetrachloro-isophthalonitrile, 0.66 mg (0.625 ml of Bravo 6F diluted 1:50). A slightly different formula of CNS was also published by Vidaver and Davis (1988). Lithium chloride was reported to be transiently toxic to newly isolated *Clavibacter michiganensis* subsp. *nebraskensis*. This can be overcome either by omitting it from the medium or by allowing the plant suspension to stand in a buffer containing sodium for 1–2 h before streaking (Vidaver and Davis, 1988; Zinniel et al., 2002). The medium should also be pretested to determine growth of single colonies in the presence of polymyxin B sulfate preparations, and the concentration of this antibiotic may be reduced (Vidaver and Davis, 1988). SCM agar supports selective isolation of *Clavibacter michiganensis* subsp. *michiganensis* (Fatmi and Schaad, 1988; Vidaver and Davis, 1988). Medium 4m1 (Atlas and Parks, 1993) and semiselective NCP medium (De la Cruz et al., 1992) were proposed for isolation of *Clavibacter michiganensis* subsp. *sepedonicus*. Medium D2 (Kado and Heskett, 1970) was reported to be selective for various coryneforms.

Medium 4m1 (Atlas and Parks, 1993)

Peptone	3 g
Pancreatic digest of casein	3 g
Yeast extract	3 g
Maltose	2 g
Lactose	1 g
Sodium dichromate solution	0.05 g
Agar	15 g
Water	900 ml

pH 7.0–7.2

Sodium dichromate (0.05 g in 100 ml of distilled water) is sterilized separately and added to sterile medium, cooled to 45–50°C.

ISOLATION OF SAPROPHYTIC CLAVIBACTERIA

Saprophytic clavibacteria can be isolated from different plants and some other environmental sources outlined in the subsection Habitat in this Chapter. Early summer, late summer or early autumn (Zinniel et al., 2002; Jacobs and Sundin, 2001) or spring and summer in desert regions (Dobrovolskaya et al., 1999) are suitable sampling periods. Jacobs and Sundin (2001) found that the late summer period was the best sampling time for isolation of UV-tolerant clavibacteria inhabiting field-grown peanut plants. As larger bacterial populations are located on the adaxial surface of leaves (Beattie and Lindow, 1995; Sundin and Jacobs, 1999), this site of leaves is preferable for isolation of epiphytes. To isolate clavibacteria from the phyllosphere of plants, the dilution or leaf impression techniques described by Dickinson et al. (1975), Dunleavy (1989), Behrendt et al. (1997), and Jacobs and Sundin (2001) may be used. Important points are sterile sampling and transport of plants in ice to the laboratory and use of media supplemented with antifungal antibiotics. For isolation of endophytic clavibacteria, the approaches described by Hallmann et al. (1997), Fisher et al. (1992) or Zinniel et al. (2002) may be applied. Surface disinfestation, e.g., with 2% sodium hydrochloride containing 0.1% Tween 20 for 10 s followed by several washes in sterile water or buffer solutions, is an important stage of isolating endophytic bacteria as it significantly reduces (by more than 10,000-fold) external contamination with epiphytic bacteria (Zinniel et al., 2002). Surface detergents, like Tween 20, Tween 80 or Triton X-100, reduce surface tension of the solvent, allowing the disinfectant to reach protected sites and grooves beyond collapsed epidermal cells on the plant surface. Another surface disinfestation technique involves dipping plant tissue into ethanol and flaming of the surface (Dong et al., 1994).

NBY medium, CNS medium (Gross and Vidaver, 1979a), and a modified CNS medium without lithium chloride were successfully used for isolation of the epiphytic and endophytic

clavibacteria (Zinniel et al., 2002). They may also be isolated and grown on tryptic soy agar, R2A agar, CB agar, or other media based on peptone, yeast extract, and glucose. *Clavibacter* strains usually grow well at 24–26°C. Incubation at room temperature (18–24°C) in daylight facilitates better formation of pigment that allows one to differentiate some clavibacteria from other bacteria at the earlier stage of investigation.

Identification

GENERIC LEVEL Irregular, nonsporeforming rods isolated from different sources can be easily identified as members of the genus *Clavibacter* by using 16S rDNA sequence analysis and/or some phenotypical properties listed in Table 1. Partial sequence (5'400–500 nucleotides) of 16S rDNA or restriction analysis of amplified 16S rDNA (Lee et al., 1997b; Lee et al., 1997a; Behrendt et al., 2002) is usually discriminatory enough to assign isolates to clavibacteria. Identification based on phenotypic traits involves mainly the detection of DAB in the cell wall and the major menaquinone MK-9. However, as new organisms with the same or similar chemotaxonomic characteristics may occur in different plants or other environments, at least partial 16S rDNA nucleotide sequencing is recommended for determining genus affiliation.

SPECIES LEVEL Cultural, physiological and biochemical features (Table 4) and polyacrylamide gel electrophoresis of soluble proteins (Carlson and Vidaver, 1982) are useful to compare new strains from unusual sources with *Clavibacter michiganensis* subspecies. Fatty acid analysis, rep-polymerase chain reaction (PCR)-mediated genomic fingerprinting (Louws et al., 1998) and Fourier-transform infrared (FT-IR) spectroscopy, which reflects common physical-chemical profiles of bacterial cells (Behrendt et al., 2002; Oberreuter et al., 2002), may also be helpful. Affiliation of saprophytic strains from an unusual host to a valid species requires DNA-DNA relatedness studies or analysis of other genomic characteristics of adequate resolving power (Vandamme et al., 1996; Stackebrandt et al., 2000, 2002; Rossello-Mora and Amann, 2001).

IDENTIFICATION AND DETECTION OF *CLAVIBACTER MICHIGANENSIS* SUBSPECIES *General approaches*

The phytopathogenic clavibacteria are relatively easy to identify when isolated from young lesions of the known hosts with characteristic symptoms as a predominant fraction of the microbial community and compared with known pathogens (Vidaver and Davis, 1988). Colony characteristics on NBY agar or other media, growth on

^{a,b,c,d,e}The opposite results were reported by Zgurskaya (1993a), Dye and Kemp (1977), Davis et al. (1984b), Vidaver and Davis (1988), and Behrendt et al. (2002), respectively, using different methods.

^fData from Carlson and Vidaver (1982). Somewhat different values of the G+C content of DNA were reported by other authors.

^gData from Vidaver (1982).

Adapted from Dye and Kemp (1977), Carlson and Vidaver (1982), Davis et al. (1984b), Vidaver and Davis (1988), Zgurskaya (1993a), and Behrendt et al. (2002).

CNS agar and TTC agar (glucose, 5 g; peptone, 10 g; casein hydrolysate, 1 g; 2,3,5-triphenyltetrazolium chloride, 0.05 g; agar, 17 g; and water, 1 liter), Gram-positive identification with KOH (Ryu, 1938; Suslow et al., 1982), coryneform morphology (bending type of cell division without a strong tendency for a rod-coccoid cycle), catalase positive and usually oxidase negative reactions, and some other physiological properties (Table 4) are helpful identifying traits. Along with *Clavibacter michiganensis* subspecies, some saprophytic bacteria of other taxa with similar properties may be isolated, especially at the early stages of infection or from old necrotic areas and rotten parts, and an additional confirmation of identification is necessary by using the

approaches outlined in the previous subsection. A direct test for virulence on the host or indicator plants or induction of hypersensitive reaction on non-host plants is the appropriate procedure for confirmation or identification of plant pathogenic *Clavibacter michiganensis* (Vidaver and Davis, 1988; Collins and Bradbury, 1992). However, a successful pathogenicity test may prove difficult if the right plants at the right stage of growth are not available (Collins and Bradbury, 1992). In addition, naturally occurring avirulent *Clavibacter michiganensis* subsp. *michiganensis* strains in diseased plants occur (Louws et al., 1998). Identification and confirmation are also possible by different DNA-based techniques or serological tests.

DNA-based methods DNA-based methods offer alternative ways for rapid, highly sensitive, specific detection and identification of plant pathogenic clavibacteria. Originally, DNA hybridization assays to detect and diagnose bacterial ring rot, wilt, and canker in tomato (Johansen et al., 1989; Thompson et al., 1989; Rademaker et al., 1992) were proposed. A PCR technique and specific PCR-primers targetting genomic or plasmid DNAs were developed for detection of *Clavibacter michiganensis* subsp. *sepedonicus* and *Clavibacter michiganensis* subsp. *michiganensis* (Firrao and Locci, 1994; Rademaker and Janse, 1994; Dreier et al., 1995; Hu et al., 1995; Li and De Boer, 1995a; Li and De Boer, 1995b; Slack et al., 1996; Lee et al., 1997a; Mills et al., 1997; Santos et al., 1997; Louws et al., 1998; Jahr et al., 1999; Brown et al., 2002).

A rapid and effective method to identify strains of *Clavibacter michiganensis* subspecies is based on rep-PCR-mediated genomic fingerprinting (Louws et al., 1998). Naturally occurring avirulent *Clavibacter michiganensis* subsp. *michiganensis* strains had rep-PCR fingerprints similar to those of virulent strains of this subspecies (Louws et al., 1998). Nested PCR for ultrasensitive detection of *Clavibacter michiganensis* subsp. *sepedonicus* is based on oligonucleotide primers derived from sequences of the 16S rRNA gene and insertion element IS1121 of this bacterium (Lee et al., 1997a). The method allows detection of very low titers of *Clavibacter michiganensis* subsp. *sepedonicus* in symptom-less potato plants or tubers, which cannot be readily detected by direct PCR (single PCR amplification). Specific detection of *Clavibacter michiganensis* subsp. *sepedonicus* based on amplification of three unique DNA sequences isolated by subtraction hybridization was proposed (Mills et al., 1997). The lowest level of detection of *C. michiganensis* subsp. *sepedonicus* was 100 colony forming units (CFU) per milliliter when cells were added to potato core fluid. Genomic fingerprints of *Clavibacter michiganensis* subsp. *sepedonicus* generated by contour-clamped homogeneous electric field (CHEF) gel electrophoresis of restriction enzyme digested high-molecular weight DNA may be useful to detect genomic variability associated with virulent and avirulent strains of this subspecies (Brown et al., 2002). The sequence information on the endoglucanase (*celA*) gene and the *pat-1* gene encoding serine protease is helpful for detection of *Clavibacter michiganensis* subsp. *michiganensis* (Dreier et al., 1995; Dreier et al., 1997; Jahr et al., 1999; Jahr et al., 2000). A DNA probe derived from the *celA* gene differentiated between *Clavibacter michiganensis* subsp. *michiganensis* and other subspecies. A probe derived from the *pat-*

1 gene is more specific, giving a hybridization signal exclusively with virulent strains of *Clavibacter michiganensis* subsp. *michiganensis*. PCR primers based on the sequence of this gene permit detection of virulent strains of *Clavibacter michiganensis* subsp. *michiganensis* in homogenates prepared from infected plants and naturally contaminated seeds. A positive result was obtained with as few as 2×10^2 bacteria per ml of contaminated plant homogenate (Jahr et al., 1999).

Serological Methods Serological methods are very sensitive and particularly useful for detection of clavibacteria in symptomless infections. Immunofluorescence allows direct observation of cells in the plant host and was reported to be useful for detection of almost all *Clavibacter michiganensis* subspecies (Lelliott and Stead, 1987). The most widely used serological approaches for detection of *Clavibacter michiganensis* subsp. *michiganensis* and *Clavibacter michiganensis* subsp. *sepedonicus* are the enzyme-linked immunosorbent assay (ELISA) and immunofluorescence based on monoclonal antibodies (De Boer and Wieczorek, 1984a; De Boer et al., 1984b; Drennan et al., 1993; Dreier et al., 1995). Occasionally, problems with cross-reacting bacteria may occur (De Boer, 1991; Li and De Boer, 1995b; Slack et al., 1996). Bioassay is sometimes used to complement these tests (Li and De Boer, 1995b). A rhodamine-labelled oligonucleotide probe has been used in conjunction with an indirect immunofluorescence procedure based on a specific monoclonal antibody detected with a fluorescein-labelled conjugate. Simultaneous labelling of bacterial cells with the oligonucleotide and antibody probes was found to allow accurate microscopic identification of single cells of *Clavibacter michiganensis* subsp. *sepedonicus* when isolation and other methods of confirming bacterial identity are hampered or impossible (Li et al., 1997).

Preservation

The principles outlined in the subsection Preservation in this Chapter for *Microbacterium* Species should be followed.

Freeze-drying may sometimes affect virulence of plant pathogens (Servin-Massieu, 1971). Virulence of *Clavibacter michiganensis* subsp. *nebraskensis* and probably other subspecies can be maintained satisfactorily by storage on solid complex media at 6°C for 2 years or by lyophilization. Storage of *Clavibacter michiganensis* subsp. *nebraskensis* in sterile distilled water or phosphate buffer at 6°C or room temperature was unsatisfactory for maintenance of viability and virulence; strains maintained in dried leaves

of greenhouse grown plants were viable and virulent up to three months (Vidaver, 1977).

Applications

The physiological and enzymatic activities of wildtypes and mutants of *Clavibacter* spp., including those related to plant pathogenesis, provide evidence that clavibacteria are a potential target for screening metabolites, enzymes and genes to be used in biotechnology, medicine, the food industry, and agriculture. Results obtained during studying the effect of polysaccharides on immunologic factors in animals with *Mycoplasma hominis* infection and histomorphological data showed that polysaccharides of *Clavibacter michiganensis* are immunomodulators (Rudenko et al., 1996). A glycopolymer of *Clavibacter michiganensis* was found to induce γ -interferon (Varbanets et al., 1990a) and acid polysaccharides to induce formation of the tumor necrosis factor and interleukin-1 by peritoneal macrophages of mice (Varbanets et al., 1990b). Extracellular polysaccharides produced by clavibacteria are an easy source of clavan, an L-fucose rich polymer, and some unusual monosaccharides (Vanhooren and Vandamme, 1999; Vanhooren and Vandamme, 2000). L-Fucose can be used in medicine for prevention of tumor cell colonization of the lung, controlling white blood cell formation, rheumatoid arthritis treatment, antigen synthesis for antibody production, and such "cosmeceuticals" as a skin moisturizing agent. Clavibacteria produce different biotechnologically applicable enzymes, e.g., oxoglutarate-dehydrogenase used for production of optically active γ -hydroxy-L-glutamic acid (Katsumata and Hashimoto, 1996), specific β -glucosidases (Kiso et al., 2000), and some others. *Clavibacter michiganensis* strain ATZ1 catabolizes triazine herbicides (Seffernick et al., 2000). Cell extracts from this bacterium, which contains a gene homologous to the atrazine chlorohydrolase (AtzA) gene in *Pseudomonas* sp. strain ADP, were able to transform atrazine analogs containing pseudohalide and thiomethyl groups, in addition to the substrates transformed by AtzA from *Pseudomonas* sp. Clavibacteria can also degrade bacterial and synthetic polyesters (e.g., poly- β -hydroxybutyrate, etc.; Mergaert et al., 1995; Mergaert and Swings, 1996). *Clavibacter* strain ALA2 effectively oxidizes linoleic acid from vegetable oils into value-added industrial products. One of the products of the biotransformation, 12,13,17-trihydroxy-9(Z)-octadecenoic acid, was found to inhibit the growth of various plant pathogens and may be used as pesticide (Hou et al., 1997; Hou, 1998; Hou, 1999; Gardner et al., 2000).

Bacteria of the genus *Clavibacter* are also involved in recent studies related to plant disease control. Introduction of disease- and insect resistance into crops and ornamental plants by application of protein derived from a noninfectious strain of *Clavibacter michiganensis* subsp. *sepe-donicus* was described (Beer and Butler, 1999). The approach involves applying a hypersensitive response-elicitor protein to plant or plant seed, resulting in a plant with a heritable disease-resistance trait. The treatment induces resistance to different pathogens, including viruses, bacteria, fungi and insects. The possible practical use of clavibacteria is related to their natural endophytic mode of life. Colonization of several crops with endophytic clavibacteria (Zinniel et al., 2002) is a promising tool for delivering enzymes to control plant diseases and other useful products promoting plant growth. This will permit growth of plants with improved capabilities without integration of foreign DNA into the plant genome; this provides an alternative to genetic modification or breeding of plants, which is costly, depends on the plant variety being studied, and may take several years to reach the market (Zupan and Zambryski, 1995; Hallmann et al., 1997). The finding that pathogenic clavibacteria can be converted into endophytes by transformation of plasmid DNA increases the chance of expressing gene products which will prevent infection of host plants by other pathogens (Jahr et al., 1999). A chitinase gene-carrying hybrid plasmid has been constructed that expresses this enzyme when introduced into a plasmid-free strain of *Clavibacter michiganensis* subsp. *michiganensis* (Jahr et al., 1999). Under laboratory conditions, infection of tomato plants with such a strain resulted in a reduced sensitivity to infection of plants by *Fusarium oxysporum* f. sp. *lycopersici*, a fungal pathogen of tomato. Endophytic clavibacteria or plant pathogens converted into endophytes might also be considered as potential vectors of certain foreign genes for construction of transgenic plants.

The Genus *Cryobacterium*

The genus *Cryobacterium*, including the species *Cryobacterium psychrophilum*, was proposed by Suzuki et al. (1997) as a pink, obligately psychrophilic bacterium, which had been previously described by Inoue and Komagata (1976) as "*Curtobacterium psychrophilum*."

The bacterium was isolated from a soil sample from Antarctica by Inoue (1976) and assigned to the genus *Curtobacterium* on the basis of its cell wall amino acid composition, found to be typical of *Curtobacterium* spp., and of its high DNA G+C content (Inoue and Komagata, 1976b). On

the basis of *Arthrobacter*-like morphology and low maximum growth temperature, the authors classified it into a new species, "*Curtobacterium psychrophilum*." However, this name was not validly published. In 1997, Suzuki et al. examined the chemotaxonomic features of this strain and found DAB in the cell wall instead of ornithine. Phylogenetic analysis based on 16S ribosomal DNA sequences demonstrated that this bacterium represents a distinct lineage within the radiation of the family Microbacteriaceae, thus representing a new genus (Suzuki et al., 1997).

Phylogeny

The phylogenetic dendrogram (Fig. 1) shows that the genus *Cryobacterium* is distant from all validly described genera of the family Microbacteriaceae, linked peripherally to the genus *Agrococcus* (Groth et al., 1996).

Taxonomy

The only species of the genus, *Cryobacterium psychrophilum*, is characterized by a growth temperature optimum at 9–12°C and no growth at temperatures higher than 18°C. Colony color is pink to reddish-orange. Cells are nonmotile, nonsporeforming, pleomorphic rods. Branching and coccoid forms may occur in the early growth phase and in old culture, respectively. Aerobic, catalase and oxidase are positive. Amino acids of the cell wall peptidoglycan are 2,4-diaminobutyric acid (mainly L-isomer), alanine, glycine, and glutamic acid in the molar ratio consistent with B2γ peptidoglycan (Schleifer and Kandler, 1972). Muramic acid of the peptidoglycan is of acetyl type. Rhamnose and fucose are characteristic cell wall sugars. The main cellular fatty acids are *iso*- and *anteiso*-branched acids. 12-Methyl tetradecenoic acid (*anteiso*-15:1) accounts for 20–26% of the cellular fatty acids in cells grown at 4–10°C. The major menaquinone is MK-10, followed by MK-11 and MK-8. The polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and glycolipid. The G+C content of DNA is approximately 65 mol% (Inoue and Komagata, 1976b; Suzuki et al., 1997; Sasaki et al., 1998).

Habitat

The only strain of *Cryobacterium psychrophilum* was isolated from a soil sample from an area inhabited by plants or animals, collected near Showa Station in Antarctica, the East Ongul Island (the maximum temperature is about +7°C on coastal islands; Inoue, 1976a). The temperature condition of soil from which the strain was isolated, the growth temperature range (<18°C) of the strain, and its fatty acid composition (high

amount of *anteiso*-15:1 used to maintain membrane fluidity at low temperatures; Suzuki et al., 1997), suggest an active state of *Cryobacterium psychrophilum* in soil under permanently low temperatures.

Isolation

Cryobacterium psychrophilum was isolated at 0°C using PYG agar (Inoue and Komagata, 1976b) from a sample stored at 5°C within a few hours after sampling (Inoue, 1976a). Since mesophilic species of the genus may exist in nature, higher temperatures should be tested during the isolation regime. No special media are used for cultivation of heterotrophic microorganisms of the genus *Cryobacterium*. A number of media, including PYG agar (Inoue and Komagata, 1976b) or R agar (Yamada and Komagata, 1972a; Suzuki et al., 1997), are suitable.

PYG agar (Inoue and Komagata, 1976b)

Peptone	1 g
Yeast extract	5 g
Glucose	3 g
Agar	15 g
Water	1 liter
pH 7.2	

Identification

Pink to orange-red colonies, the presence of DAB in cell wall, the major menaquinone MK-10, growth temperature range, and unique cellular fatty acid profile (particularly a significant amount of 12-methyl tetradecenoic acid; Table 1) are good grounds for preliminary identification of *Cryobacterium psychrophilum* at the phenotypic level. Although this fatty acid is also accumulated in cells of some mesophilic strains grown at 10°C, its amount does not exceed 8% (Suzuki et al., 1997). Cell size (0.5–0.7 × 1.0–1.8 μm), cell wall sugar composition, positive DNase test, production of acids from fructose, mannose, glucose, galactose, and sucrose, utilization of lactate, pyruvate, fumarate, and hippurate, low utilization of many other C-sources tested (Inoue and Komagata, 1976b; Suzuki et al., 1997), and probably growth temperature optimum are the basis of its discrimination from other species of the genus, which are yet to be isolated and described.

The Genus *Curtobacterium*

The genus *Curtobacterium* was established by Yamada and Komagata (1972b) for a group of coryneform bacteria that contained ornithine in the cell wall and weakly produced acid from various carbohydrates.

In *Bergey's Manual of Systematic Bacteriology* (Komagata and Suzuki, 1986), five species were included in the genus: *Curtobacterium albidum*, *Curtobacterium citreum*, *Curtobacterium luteum*, *Curtobacterium pusillum* (Yamada and Komagata, 1972b) and *Curtobacterium flaccumfaciens* with pathovars (Collins and Jones, 1983b). Behrendt et al. (2002) have recently described a sixth species, *Curtobacterium herbarum*, which was isolated from the phyllosphere of grasses and the surface litter after mulching the sward. Another plant-associated saprophyte species, *Curtobacterium plantarum*, was proposed by Dunleavy (1989). However, the type strain CL63^T (ATCC 49174^T, DSM 7069^T) of this species has an A-type peptidoglycan, and according to 16S rDNA sequence and fatty acid pattern, should be placed into the genus *Pantoea* (Deutsche Sammlung von Mikroorganismen und Zellkulturen, 1998). As judged from the current knowledge on the occurrence of curtobacteria in different plants (see subsection Habitat in this Chapter), the physiological heterogeneity of strains assigned to *Curtobacterium plantarum*, and the similarity in physiological traits to authentic curtobacteria (Dunleavy, 1989), it might be argued that many strains isolated by Dunleavy were in fact members of the genus *Curtobacterium*.

Since 1922 (Hedges, 1922), organisms comprising the current genus *Curtobacterium* have been assigned to different bacterial genera, e.g., "*Bacterium*," "*Phytomonas*," "*Pseudobacterium*," *Corynebacterium* and *Brevibacterium* (Cummins et al., 1974). By 1972, most of them had been placed within the genera *Brevibacterium* and *Corynebacterium* (Komagata and Iizuka, 1964; Iizuka and Komagata, 1965; Cummins et al., 1974). In an exhaustive taxonomic study of various coryneforms, Yamada and Komagata (1972b) established a new genus *Curtobacterium* for obligately aerobic organisms with ornithine in the cell wall, a high DNA G+C content (66–71 mol%), and weak production of acid from some sugars. The new genus differed from *Cellulomonas*, the other genus known to have ornithine in the cell wall at that time, by the mode of cell division and some physiological properties. The species assigned to the genus *Curtobacterium* included several former *Brevibacterium* spp. (*B. albidum*, *B. citreum*, "*B. helvolum*," "*B. insectiphilum*" and *B. luteum* [Komagata and Iizuka, 1964], *B. pusillum* [Iizuka and Komagata, 1965], *B. saperdae* [Lysenko, 1959], *B. testaceum* [Komagata and Iizuka, 1964]), as well as *Corynebacterium flaccumfaciens* (Hedges, 1922; Dowson, 1942) and *Corynebacterium poinsettiae* (Starr and Pirone, 1942), the only plant pathogens with ornithine in their cell walls included in the study of Yamada and Komagata (1972a).

Further investigations (Schleifer and Kandler, 1972; Fiedler et al., 1973b; Yamada et al., 1976; Uchida and Aida, 1977; Collins et al., 1979; Collins et al., 1980b) showed the peptidoglycan structure and menaquinone composition of organisms assigned to this genus were heterogeneous. Consequently, only the non-phytopathogenic species *Curtobacterium albidum*, *Curtobacterium citreum*, *Curtobacterium luteum*, *Curtobacterium pusillum*, *Curtobacterium saperdae* and *Curtobacterium testaceum* were included in the Approved Lists of Bacterial Names (Skerman et al., 1980). The two latter species were transferred to the genus *Aureobacterium* (Collins et al., 1983c) as they contained N-glycolyl residues in the glycan moiety of their walls (Uchida and Aida, 1977), an additional glycine residue in the interpeptide bridge of their peptidoglycan (Schleifer and Kandler, 1972; Collins et al., 1983c), and unusually long menaquinones (MK-11, MK-12; Collins et al., 1980b; Collins et al., 1983c), properties which were in contrast to authentic members of the genus *Curtobacterium* (Table 1). The genera *Aureobacterium* and *Microbacterium* were later united under *Microbacterium* (Takeuchi and Hatano, 1998b).

"*Curtobacterium helvolum*" and "*Curtobacterium insectiphilum*," proposed by Yamada and Komagata, were not approved (Skerman et al., 1980) and have not been approved since then. Four strains of "*Brevibacterium helvolum*" studied by Yamada and Komagata (1972b) were determined to contain B2γ peptidoglycan based upon DAB (Schleifer and Kandler, 1972). "*Brevibacterium helvolum*" DSMZ 20419 (ATCC 13715), having the same peptidoglycan type (Schleifer and Kandler, 1972; Fiedler et al., 1973b), was shown to represent a separate line of descent within the family Microbacteriaceae and suggested to represent the nucleus of a new genus (Rainey et al., 1994; see the section Other Microorganisms of the Family Microbacteriaceae in this Chapter). Strain "*Brevibacterium helvolum*" ATCC 11822 is a soil isolate originally referred by Jensen (1934) to *Corynebacterium helvolum* but showing morphological and chemotaxonomic characteristics typical of the genus *Arthrobacter* (Yamada and Komagata, 1972b; Fiedler et al., 1973b; Yamada et al., 1976). Other strains labelled "*Brevibacterium helvolum*" are also doubtful members of the genus *Curtobacterium* as the earlier descriptions of this species were contradictory. No phylogenetic or detailed chemotaxonomic data are available with regard to "*Curtobacterium insectiphilum*" AJ 1477 (JCM 1348, IFM AM-23; Yamada and Komagata, 1972b), except for the fatty acid composition which is similar to that of *Curtobacterium* spp. (Suzuki and Komagata, 1983).

"*Brevibacterium insectiphilum*" strain Bhat 146 is phylogenetically closest to *Microbacterium* spp. (Döpfer et al., 1982) and possesses the cell wall peptidoglycan type B2 β , [L-Hsr]-D-Glu(Hyg)-Gly-D-Orn (Schleifer and Kandler, 1972), typical of *Microbacterium*.

Besides *Corynebacterium flaccumfaciens* and *Corynebacterium poinsettiae* (Yamada and Komagata, 1972a; Yamada and Komagata, 1972b), two other plant pathogenic species, i.e., *Corynebacterium betae* (Keyworth et al., 1956) and *Corynebacterium oortii* (Saaltink and Maas Geesteranus, 1969), were found to be similar to *Curtobacterium* in chemotaxonomic properties (Schleifer and Kandler, 1972; Yamada et al., 1976; Collins et al., 1979; Collins et al., 1980b) and DNA base ratios (Starr et al., 1975). Also *Corynebacterium betae* was indicated to be similar to *Curtobacterium* spp. on the basis of numerical taxonomic study (Jones, 1975). However, these four plant pathogenic species were listed in the Approved Lists under the generic name *Corynebacterium*. On the basis of nearly identical cellular protein patterns and some other taxonomic characteristics, these four plant pathogens were unified into one species, *Corynebacterium flaccumfaciens* (Carlson and Vidaver, 1982), in accord with the opinion of Dye and Kemp (1977), expressed previously on the basis of high overall phenetic similarity. But in contrast to Dye and Kemp, who treated these four species as pathovars, Carlson and Vidaver (1982) proposed that the traditional names of pathogens in the subspecies be retained and reclassified them into four subspecies. The proposal was substantiated by differences in some biochemical characteristics (Dye and Kemp, 1977), bacteriocin production (Gross and Vidaver, 1979b), preliminary data on low level of DNA-DNA relatedness between two pathovars (Starr et al., 1975), and also host specificity. The subspecies were validated (Moore et al., 1985) as *Corynebacterium flaccumfaciens* subsp. *flaccumfaciens* (Hedges 1922) Dowson 1942; Collins et al. 1979, *Corynebacterium flaccumfaciens* subsp. *betae* (Keyworth et al., 1956; Collins et al., 1979) Carlson and Vidaver, 1982 Collins et al. 1979, *Corynebacterium flaccumfaciens* subsp. *oortii* (Saaltink and Maas Geesteranus, 1969), and *Corynebacterium flaccumfaciens* subsp. *poinsettiae* (Starr and Pirone, 1942; Collins et al., 1979) Carlson and Vidaver 1982.

Later, Collins and Jones (1983b) transferred these plant pathogens to the genus *Curtobacterium* based on the chemotaxonomic data (Schleifer and Kandler, 1972; Yamada et al., 1976; Keddie and Cure, 1978; Collins et al., 1979; Collins et al., 1980b; Collins et al., 1982b). Collins and Jones (1983b) proposed to lower the rank of *Curtobacterium flaccumfaciens* subspecies to the

level of pathovars, taking into account the high degree of DNA-DNA relatedness (Döpfer et al., 1982) and close physiological relationship (Dye and Kemp, 1977). Differences in host specificity and bacteriocin production were thus considered insufficient to justify differentiation at the sub-specific level (Collins and Jones, 1983b).

Further taxonomic studies are required to elucidate the species structure of the genus *Curtobacterium* and taxonomic ranks of the infraspecies groups comprising *Curtobacterium flaccumfaciens*. Such taxonomic revision is necessary from practical and regulatory points of view. The necessity of such revision is further substantiated by phenotypic differences between the pathovars of *Curtobacterium flaccumfaciens* (Table 6) as well as by information on the isolation of many new *Curtobacterium flaccumfaciens* strains and close relatives from unusual hosts (Raupach and Kloepper, 2000; Araujo et al., 2001) or different non-diseased plants worldwide (Legard et al., 1994; Dobrovolskaya et al., 1999; Elbeltagy et al., 2000; Behrendt et al., 2002; Zinniel et al., 2002; L. I. Evtushenko et al., unpublished observation).

Phylogeny

Members of the genus *Curtobacterium* form a tight (100% bootstrap confidence) phylogenetic cluster within the radiation of bacteria comprising the family Microbacteriaceae (Fig. 1).

Taxonomy

The genus *Curtobacterium* sensu stricto currently harbors the following six species:

Curtobacterium albidum (Komagata and Iizuka, 1964), *Curtobacterium citreum* (Komagata and Iizuka, 1964), *Curtobacterium luteum* (Komagata and Iizuka, 1964), *Curtobacterium pusillum* (Komagata and Iizuka, 1964) all Yamada and Komagata 1972b, *Curtobacterium flaccumfaciens* (Hedges, 1922) Collins and Jones, 1984, and *Curtobacterium herbarum* (Behrendt et al., 2002).

The characteristics typical of the genus can be summarized as follows. Colonies on nutrient agar are yellow, orange or ivory, shiny, slightly convex and round, with entire margins. Cells are small, irregular, unbranched rods, tending to become shorter in the older culture and multiply by the bending type of cell division. These Gram-positive, nonsporeforming cells usually move by means of lateral flagella and are obligately aerobic, catalase positive, chemoorganotrophic, mesophilic, and capable of growth on a nutrient agar and related media. Growth usually occurs at 5% NaCl but not at 10% NaCl. Acid is produced rather slowly and weakly from carbohy-

drates. The cell wall peptidoglycan based upon D-ornithine is of the type B2 β , [L-homoserine]-D-Glu-D-Orn (Schleifer and Kandler, 1972). The glycan moiety of the peptidoglycan contains acetyl residues (Uchida and Aida, 1977). Mycolic acids are not present. The predominant fatty acids are *anteiso*-15:0, *anteiso*-17:0 with substantial amounts of *iso*-16:0, and some others (Collins et al., 1980b; Stead, 1988). ω -Cyclohexyl undecanoic acid may occur in some representatives of the genus (Suzuki and Komagata, 1983). Polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and some glycosyldiacylglycerols; the major respiratory quinone is unsaturated menaquinone with nine isoprene units (Collins et al., 1980b). The DNA G+C content is 68.3–75.2 mol% (Yamada and Komagata, 1970; Döpfer et al., 1982; Behrendt et al., 2002).

The species differentiation is based on growth characteristics, content of G+C of DNA, fatty acid composition, and some physiological properties (see subsection Identification in this Chapter).

Habitat and Phytopathogenicity

The data available suggest that the main natural habitat of *Curtobacterium* spp. are different plants and related sources, although they also occur in soil and other environments (Iizuka and Komagata, 1965; Lednicka et al., 2000; Koneva and Kruglov, 2001). Among validly described species of the genus, only *Curtobacterium pusillum*, recovered from oil brine in a Japanese oil field (Iizuka and Komagata, 1965), was found outside plants. *Curtobacterium albidum*, *Curtobacterium citreum* and *Curtobacterium luteum* were first isolated from Chinese rice paddies (Komagata and Iizuka, 1964). *Curtobacterium herbarum* inhabits the phyllosphere of grasses and the surface litter after mulching the sward (Behrendt et al., 2002). *Curtobacterium flaccumfaciens* is the only species of the genus for which plant pathogenic properties were recorded (Young et al., 1996).

OCCURRENCE OF PLANT-ASSOCIATED SAPROPHYTIC CURTOBACTERIA *Curtobacterium* along with representatives of the genera *Clavibacter*, *Pseudomonas*, *Pantoea* and *Stenotrophomonas* were reported to be numerically predominant in the microbial communities of grass phyllosphere and in decaying surface litter after sward mulching (Behrendt et al., 1997; Behrendt et al., 2002). Strains of the genus *Curtobacterium* and *Clavibacter* have been isolated at every sampling and, in comparison with the Gram-negative bacteria, often formed a greater fraction. Dunleavy (1989) found organisms resembling *Curtobacterium* morphologically and physiologically in leaves of

about 200 species comprising 62 plant families, including herbs, shrubs and trees from a widespread area in the state of Iowa (United States). This is consistent with the finding of properly identified curtobacteria in leaves and seeds of different plants of the families Asteraceae, Cyperaceae, Poaceae and Lamiaceae and also in moss in Russia (L. I. Evtushenko et al., unpublished observation). Curtobacteria were also isolated from various plants and related sources collected in desert areas in Uzbekistan, Turkmenistan and Israel (Dobrovolskaya et al., 1999). As the isolation methods involved no surface disinfection, it is unclear whether the saprophytic curtobacteria were epiphytes or endophytes (Kado, 1992) living in plant tissues without doing substantive harm or gaining benefit other than residency. *Curtobacterium flaccumfaciens* was found in various plants without disease symptoms, e.g., in the phyllosphere of weeds (Vidaver, 1982), grasses (Behrendt et al., 2002), sugar beet (Thompson et al., 1993), field-grown peanut (Sundin and Jacobs, 1999), and spring wheat (Legard et al., 1994).

Zinniel et al. (2002) showed that curtobacteria can exist as endophytes. Endophytic bacteria identical in 16S rDNA sequences and fatty acid profiles to *Curtobacterium flaccumfaciens* were observed within agronomic crops. Endophytes phylogenetically related to *Curtobacterium citreum* were found in wild and traditionally cultivated rice varieties (Elbeltagy et al., 2000). A group of endophytic curtobacteria was recovered among other bacteria, which colonized the foliage, tap roots, and nodules of red clover plants (*Trifolium pratense* L.; Sturz et al., 1997). Moreover, in root bacterization experiments, bacteria identified as *Curtobacterium luteum* consistently promoted growth of the plant either individually or in combination with *Rhizobium* sp. (Sturz et al., 1997). Different strains of the genus *Curtobacterium* together with *Microbacterium* strains, including *M. testaceum*, were isolated from plant galls induced by plant parasitic nematodes of the subfamily Anguininae in seeds, leaves and stems of their host plants (Evtushenko et al., 1994). In some seed galls of *Agrostis* sp., they composed up to 90% bacterial isolates developed on CB agar (L. I. Evtushenko, unpublished observation). It has not yet been verified whether these curtobacteria are carried into the growing points of host plants like *Rathayibacter* spp. by seed gall nematodes, *Anguina* spp. (Price et al., 1979; Riley and Ophel, 1992), and develop inside plant galls primordially, or whether they are secondary settlers of the galls, descending from the phyllosphere or healthy plant tissue. Data regarding their plant pathogenic properties are also missing.

PLANT HOSTS AND OCCURRENCE OF PHYTOPATHOGENIC *CURTOBACTERIUM FLACCUMFACIENS* The main habitat of pathovars of *Curtobacterium flaccumfaciens* is considered to be their respective plant hosts. *Curtobacterium flaccumfaciens* pv. *flaccumfaciens* causes the wilt of beans, i.e., *Phaseolus* species, *Glycine max* (L.) Merr., *Vigna radiata* (L.) R. Wilczek, *Vigna angularis* (Willd.) Ohwi and H. Ohashi. *Curtobacterium flaccumfaciens* pv. *betae* infects red beet (*Beta vulgaris* L.), inducing wilt and silvering of leaves. *Curtobacterium flaccumfaciens* pv. *oortii* is a causative agent of wilt and spots of leaves and bulbs of tulips (*Tulipa* spp.) and *Curtobacterium flaccumfaciens* pv. *poinsettiae* causes stem canker and leaf spots of poinsettia (*Euphorbia pulcherrima* Willd. ex Klotzsch) (Cummins et al., 1974; Hayward, 1974; Vidaver, 1982; Collins and Bradbury, 1992; ICMP, 1997). The plant pathogens are considered poor survivors in soil; survival requires association with diseased plants or residue materials (Vidaver, 1982). Epiphytic survival on, and natural infection of, weeds has been reported for *Curtobacterium flaccumfaciens* pv. *flaccumfaciens* (Schuster and Coyne, 1974; Vidaver, 1982). Plant pathogenic curtobacteria are usually transmitted by residue materials or seed (Richardson, 1979; Richardson, 1983) or may be transmitted by rain, wind, or insects, like other bacteria occurring in plants (Lindemann and Upper, 1985; Hirano et al., 1996; Lilley et al., 1997).

The strains identified as *Curtobacterium flaccumfaciens* have recently been isolated from macerated leaf tissues of several citrus rootstocks (Araujo et al., 2001) and also shown to be a control agent for cucumber (Raupach and Kloepper, 2000). Organisms which resemble physiologically and biochemically *Curtobacterium flaccumfaciens* pv. *poinsettiae* and *Curtobacterium flaccumfaciens* pv. *flaccumfaciens* have been found in fasciated mugwort (*Artemisia vulgaris* L.; Battikhi, 2002). However, no genomic data are available which would support taxonomic affiliation of these organisms.

Pathogenicity Factors Little information is available on the pathogenicity factors of *Curtobacterium flaccumfaciens*. The evidence of enzymatic activity as a pathogenicity factor of *Curtobacterium flaccumfaciens* is indirect. An unidentified macerating agent was reported for *Curtobacterium flaccumfaciens* pv. *betae* (Kern and Naef-Roth, 1971) and will probably also be found in other subspecies. Earlier histological work on vascular pathogens, including *Curt. flaccumfaciens* pv. *flaccumfaciens*, is consistent with the interpretation of enzymatic activity preceding bacterial appearance (Nelson and Dickey, 1970; Vidaver, 1982). Electron microscopy of beans infected with *Curtobacterium flaccumfaciens* pv.

flaccumfaciens showed damage to the xylem and decomposition of the middle lamella prior to wilting (Vidaver, 1982). *Curtobacterium flaccumfaciens* possesses β -glucosidase, esterase, peptidases, lipases, etc. and has the high overall similarity to *Clavibacter michiganense* in many API ZYM tests and other experimental enzymatic API galleries (the total of 106 tests) (De Bruyne et al., 1992). In addition, the strain identified as *Curtobacterium flaccumfaciens* on the basis of the fatty acid and API 20NE profiles was able to rapidly degrade cellulosic plant fibers *in vitro* (Lednicka et al., 2000). All these data suggest a possible relatedness between *Clavibacter michiganensis* and *Curtobacterium flaccumfaciens* in ecological strategies and plant pathogenic properties. Therefore, some aspects of wilting caused by *Curtobacterium flaccumfaciens* might be similar to those of *Clavibacter michiganensis* (see the section The Genus *Clavibacter* in this Chapter).

Isolation

Saprophytic curtobacteria can be isolated together with clavibacteria from different plants and some other environmental sources (Dunleavy, 1989; Dobrovolskaya et al., 1999; Jacobs and Sundin, 2001; Behrendt et al., 2002; Zinniel et al., 2002). As larger bacterial populations are located on the adaxial surface of leaves (Beattie and Lindow, 1995; Sundin and Jacobs, 1999), this site of leaves is suitable for isolation of epiphytes by using a leaf impression technique (Dickinson et al., 1975). The methods described by Dickinson et al. (1975), Dunleavy (1989), Behrendt et al. (1997), and Jacobs and Sundin (2001) and discussed in the section The Genus *Clavibacter* in this Chapter may be used for recovering the curtobacteria from the plant phyllosphere. For isolation of endophytic microorganisms, the approaches outlined by Hallmann et al. (1997) and Fisher et al. (1992) or described by Zinniel et al. (2002) should be followed. Surface disinfection is an important stage of isolating endophytic bacteria as it significantly reduces external contamination with epiphytic bacteria (Zinniel et al., 2002). Another surface disinfection technique involves dipping plant tissue into ethanol and flaming the surface (Dong et al., 1994). CNS medium (Vidaver and Starr, 1981; Vidaver and Davis, 1988) or a modified CNS medium without lithium chloride may be used for isolation of the epiphytic and endophytic curtobacteria (Zinniel et al., 2002). They may also be isolated and grown on tryptic soy agar, R2A agar, NBY agar, PY agar, CB agar or some other media based on peptone, yeast extract and glucose (Dickinson et al., 1975; Komagata and Suzuki, 1986; Dunleavy, 1989; Evtushenko et al.,

1994; Behrendt et al., 1997). The strains usually grow well at 26–28°C, but some of them may require lower temperature for growth, 20–24°C. No selective media or special methods for enrichment have been developed for the curtobacteria nonassociated with plants.

To isolate plant pathogens, the choice of suitable diseased material is of prime importance (see the section The Genus *Clavibacter* in this Chapter). Nutrient agar supplemented with 1% glucose was noted to be a satisfactory medium for isolation and growth of plant pathogenic species *Curtobacterium flaccumfaciens* (Lelliott and Stead, 1987). Kado and Heskett (1970) reported that their selective medium D2 gave good growth of one strain each of *Curtobacterium flaccumfaciens* pv. *flaccumfaciens* and *Curtobacterium flaccumfaciens* pv. *poinsettiae*. Growth of the *Curtobacterium flaccumfaciens* pathovars occurs on CNS, but strains of *Curtobacterium flaccumfaciens* pv. *flaccumfaciens* and *Curt. flaccumfaciens* pv. *poinsettiae* may vary in growth on this medium (Vidaver and Starr, 1981).

Identification

GENERIC LEVEL The newly isolated strains can be easily identified as members of the genus *Curtobacterium* by 16S rDNA sequence analysis and/or using some phenotypical properties listed in Table 1. Observation of nonsporeforming, irregular and unbranched rods, along with detection of ornithine in cell wall and the major unsaturated menaquinone MK-9, is sufficient evidence to affiliate isolates to the genus. However, since new undescribed genera with the same or close phenotype may exist in nature, at least partial 16S rDNA nucleotide sequencing or other molecular methods are advisable to support identification. The fatty acid analysis is often used to successfully identify curtobacteria, but such identification should also be confirmed by other methods as bacteria of some genera in the family Microbacteriaceae have similar fatty acid profiles (Collins et al., 1980b; Suzuki and Komagata, 1983; Henningson and Gudmestad, 1991). ω -Cyclohexyl undecanoic acid (ch-C17:0) is a genus-specific property. This fatty acid, up to 51–64% of total cellular fatty acids, was found previously exclusively in *Curtobacterium pusillum* (Suzuki and Komagata, 1983) and has recently also been detected (up to 35%) in some new curtobacteria other than *Curtobacterium pusillum* (L. I. Evtushenko and M. Takeuchi, unpublished observation).

SPECIES LEVEL Species can be discriminated by growth and physiological features. They differ in their ability to hydrolyze starch, gelatin, and

casein, to produce acids from some carbohydrates, and in the assimilation of organic acids (Tables 5a and b). As the published data on many physiological properties of the *Curtobacterium* species vary depending on the method applied (Yamada and Komagata, 1972a; Dye and Kemp, 1977; Davis et al., 1984b; Behrendt et al., 2002), comparative study of new curtobacterial isolates and the type cultures of the known species are prerequisite for identification of the new isolates. Fatty acid analysis, especially detecting ω -cyclohexyl undecanoic acid (Suzuki and Komagata, 1983), and FT-IR spectroscopy (Behrendt et al., 2002; Oberreuter et al., 2002) are helpful approaches. Affiliation of nonpathogenic strains from plants requires DNA-DNA relatedness study or analysis of other adequate genomic characteristics (Vandamme et al., 1996; Stackebrandt et al., 2000, 2002; Rossello-Mora and Amann, 2001).

The phytopathogenic strains of *Curtobacterium flaccumfaciens* and its pathovars are relatively easy to identify when isolated from young lesions of known hosts with characteristic symptoms (Vidaver and Davis, 1988) and compared with known pathogens. Colony morphology, pigmentation, Gram-positive reaction with rapid KOH test (Ryu, 1938; Suslow et al., 1982), palisade cell arrangements in young culture, bending type of cell division without a strong tendency for rod-to-coccoid developmental cycle, some physiological properties, and cell wall sugar composition (Table 6) are helpful traits for identification. Definite identification may need confirmation by pathogenicity and/or serological tests (Vidaver and Davis, 1988), as well as some molecular methods with a taxonomic resolution at the strain-species level. *Curtobacterium flaccumfaciens* pv. *flaccumfaciens* can be identified by using PCR methods (Guimaraes et al., 2001).

Applications

The physiological and enzymatic activities of curtobacteria (Charney, 1966; De Bruyne et al., 1992; Zaczynska et al., 1992; Bark et al., 1993; Lednicka et al., 2000; Froquet et al., 2001) provide evidence that these organisms may be a potential group for screening applicable metabolites and enzymes. *Curtobacterium flaccumfaciens* pv. *flaccumfaciens* can hydrolyze steroids and might be useful in steroid transformation (Charney, 1966). *Curtobacterium flaccumfaciens* pv. *betae* produces glycolipids, which were found to potentiate interferon synthesis by peritoneal cells of BALB/c mice (Zaczynska et al., 1992). *Curtobacterium*-like strains (presumptively identified on the basis of fatty acid methyl esters [FAME] and morphology) isolated from a labo-

ratory pilot plant were found to accumulate electron-dense granules, which could be identified as polyphosphate granules. The bacteria show adenylate kinase and polyphosphate glucokinase activities (Bark et al., 1993). These features may be applied for a complex process of biological phosphate removal from wastewater. A possible approach for the practical use of curtobacteria is related to their endophytic mode of life. Colonization of several crops with endophytic bacteria (Elbeltagy et al., 2000; Zinniel et al., 2002) sug-

gests that they can be used in future applications, such as delivery of degrading enzymes for controlling of certain plant diseases or other useful products promoting plant growth (Hallmann et al., 1997). This approach would allow growth of plants with improved capabilities without integration of foreign DNA into the plant genome, alternatively to genetic modification or breeding of plants (Zupan and Zambryski, 1995). Endophytic bacteria should be also viewed as potential vectors of foreign genes for construction of

transgenic plants, although considerably more research is necessary before the practicality of this approach can be assessed.

The Genus *Frigoribacterium*

The genus *Frigoribacterium* with the type species *Frigoribacterium faeni* was proposed by Kämpfer et al. (2000) for psychrophilic strains isolated from airborne hay dust and air inside a museum. Mesophilic organisms of this genus with optimum growth at 26–28°C have recently been isolated from the phyllosphere of fescue (L. I. Evtushenko et al., unpublished observation).

Phylogeny

The strains of the genus *Frigoribacterium* showed highest 16S rRNA gene sequence similarity (up to 97%) with members of the genera *Rathayibacter* and *Clavibacter* (Kämpfer et al., 2000).

Taxonomy

The bacteria form round, convex, pale yellow or yellow colonies on the nutrient agar and can be psychrophilic and mesophilic. Cells are Gram-positive, aerobic, motile, irregular, curved or asymmetric nonsporulating rods. Mycelium is not produced. Catalase test is positive but oxidase reaction varies depending on the strain. The cell wall peptidoglycan contains D-lysine as a diamino acid; the polymer is of type B2β according to Schleifer and Kandler (1972). The glycan moiety of the peptidoglycan contains acetyl residues. The major isoprenoid quinone is menaquinone MK-9. Mycolic acids are not present.

The main fatty acids of *Frigoribacterium faeni* are 12-methyltetradecanoic acid (*anteiso*-15:0), 12-methyl-tetradecenoic acid (*anteiso*-15:1), 14-methyl-pentadecanoic acid (*iso*-16:0) and 14-methyl-hexadecanoic acid (*iso*-17:0), as well as 1,1-dimethoxy-anteisopentadecane (*anteiso*-15:0-DMA). Diphosphatidylglycerol, phosphati-

dylglycerol and an unknown glycolipid are detected in the polar lipid extracts. The DNA G+C content is approximately 71 mol% (Kämpfer et al., 2000).

Although the DNA-DNA relatedness between strains of the species *Frigoribacterium faeni* was 37–52%, the authors considered them to be different genomovars of a single species as physiological and chemotaxonomic similarity between strains was high. The phenotypic properties related to the species *Frigoribacterium faeni* are outlined in the subsection Identification in this Chapter.

Habitat

Little is known about natural habitats of microorganisms comprising the genus *Frigoribacterium*. The strains were isolated mainly from plants and plant debris. Several psychrophilic strains of *Frigoribacterium faeni* were associated with hay dust in a cattle barn, settled dust in an animal shed, and air inside a museum (Kämpfer et al., 2000). The mesophilic strain of this genus was isolated from the phyllosphere of *Festuca rubra* L. (L. I. Evtushenko et al., unpublished observation).

Isolation and Cultivation

Organisms of the genus *Frigoribacterium* can be isolated from grasses, hay or some related sources using a dilution plating method. Tryptic soy agar, CasMM agar (Altenburger et al., 1996) supplemented with cycloheximide, a tenfold diluted CB agar or R2A agar and incubation at room and lower (4–16°C) temperatures (Kämpfer et al., 2000; L. I. Evtushenko et al., unpublished observation) are suitable isolation conditions. Strains may be recovered from hay dusts as described previously (Andersson et al., 1995; Andersson et al., 1999; Altenburger et al., 1996). Organisms of the genus grow well on a number of media, including tryptic soy agar, PYES agar, CB agar, and some others at appropriate temperature conditions, 4–10°C (*Frigoribacterium faeni*) or 24–26°C (mesophilic strains).

Identification

Isolates affiliated to the family Microbacteriaceae can be readily identified as members of *Frigoribacterium* owing to the presence of lysine in the peptidoglycan and MK-9 as the major menaquinone (Table 1). In the family Microbacteriaceae, only *Okibacterium*, *Mycetocola* and eight species of *Microbacterium* possess cell wall peptidoglycans based upon lysine (Table 7). The major menaquinone MK-9 combined with the acetyl type of muramic acid and/or the G+C con-

tent of DNA (71 mol%) clearly discriminate *Frigoribacterium* from *Okibacterium*, which has the same composition and molar ratio of the peptidoglycan amino acids, and also from *Microbacterium* spp. and *Mycetocola* (Table 7). It should be noted that lysine in the cell wall and the major menaquinone MK-9 are also typical of the genus *Jonesia*, family Jonesiaceae (Rainey et al., 1995b; Stackebrandt et al., 1997). However, the latter, besides distant phylogenetic position, clearly differs from *Frigoribacterium* by the presence of serine in the cell wall, G+C content of DNA (56–58 mol%), and some other characteristics (Rainey et al., 1995b).

Helpful identifying traits of the species *Frigoribacterium faeni* are good growth at 0°C and 20°C and optimum temperature of 4–10°C, small cells (0.2–0.3 × 1.0–1.5 µm), negative oxidase reaction, assimilation of a wide variety of sugars, including *N*-acetyl-D-glucosamine, L-arabinose, *p*-arbutin, D-cellobiose, D-fructose, D-galactose, gluconate, D-glucose, D-mannose, D-maltose, L-rhamnose, D-ribose, sucrose, D-trehalose and D-xylose as well as utilization of only a few organic acids as a sole source of carbon (citrate and fumarate). Another diagnostic property of this psychrophilic species is the presence of significant amounts of *anteiso*-15:0-DMA, up to 10–30% of whole-cell fatty substances. The retention time of this compound is almost equal to that of 2-OH-14:0, according to standardized FAME analysis (Kämpfer et al., 2000). This behavior differs from the mode of cold adaptation of many other Gram-positive bacteria, which adapt by changing their ratio of *anteiso*-fatty acids to *iso*-fatty acids (Kaneda, 1991) or accumulate unsaturated fatty acid (*anteiso*-15:1), like *Cryobacterium* and some others (Suzuki et al., 1997). Besides *Frigoribacterium faeni*, DMAs were determined in bacteria of the genera *Subtercola* and *Agreia* (Männistö et al., 2000; Behrendt et al., 2002).

The Genus *Leifsonia*

The genus *Leifsonia* (Evtushenko et al., 2000) was proposed to accommodate bacteria isolated from the root galls on *Poa annua*, the water isolate “*Corynebacterium aquaticum*” (Leifson, 1962) and the plant pathogenic species *Clavibacter xyli* (Davis et al., 1984b) with two subspecies.

The first bacterium of this genus was isolated from distilled water and assigned to a new species “*Corynebacterium aquaticum*” on the basis of morphological and physiological characteristics (Leifson, 1962). Subsequent extensive taxonomic studies revealed DAB in its cell wall peptidoglycan (type B2γ, Schleifer and Kandler,

^bGlutamic acid may be substituted by 3-*threo*-hydroxyglutamic acid.

Data from Collins et al. (1983d), Takeuchi and Hatano (Takeuchi and Hatano, 1998a; Takeuchi and Hatano, 1998b), Kämpfer et al. (2000), Behrendt et al. (2001), Brennan et al. (2001), Tsukamoto et al. (2001), and Evtushenko et al. (2002).

1972), the major menaquinone with 11 and 10 isoprene units (Yamada et al., 1976; Collins et al., 1979; Collins and Jones, 1980a), and some other characteristics (Yamada and Komagata, 1972b; Komura et al., 1975; Collins et al., 1979), which indicated that “*Corynebacterium aquaticum*” was phenotypically close to the group of plant pathogenic bacteria currently belonging to *Clavibacter*, *Rathayibacter* and some other genera of the family Microbacteriaceae. Döpfer et al. (1982), studying DNA-rRNA cistron similarities of coryneform bacteria and related organisms, revealed that “*Corynebacterium aquaticum*” clustered in a homogeneous group together with all other coryneforms containing a peptidoglycan of group B. Subsequently, Park et al. (1987) showed that 5S rRNA sequence of “*Corynebacterium aquaticum*” was the closest to that of *Microbacterium testaceum*, which was the only other member of the current family Microbacteriaceae used in this study.

Phylogenetic analysis based on 16S rDNA analyses (Rainey et al., 1994; Takeuchi and Yokota, 1994) confirmed that “*Corynebacterium aquaticum*” belongs to the phylogenetic cluster composed of actinomycetes of the family Microbacteriaceae, forming a separate subline of descent within the family. The strain was suggested to be the nucleus of a novel genus (Rainey et al., 1994). Plant pathogen *Clavibacter xyli* subsp. *cynodontis* (Davis et al., 1984b) was shown to be a phylogenetic neighbor of “*Corynebacterium aquaticum*” (Takeuchi and Yokota, 1994; Sasaki et al., 1998). On the basis of the phylogenetic data and similarity in salient chemotaxonomic characteristics of “*Corynebacterium aquaticum*” and *Clavibacter xyli* subsp. *cynodontis*, Sasaki et al. (1998) postulated that a new genus should be established to accommodate these organisms. Lee et al. (1997b) showed a high level of phylogenetic similarity between *Clavibacter xyli* subsp. *cynodontis* and *Clavibacter xyli* subsp. *xyli*, which suggested the latter subspecies was another member of this genus.

Later, some coryneform bacteria isolated from the *Poa annua* root gall induced by plant parasitic nematodes of the subfamily Anguininae were shown to be phenotypically and phylogenetically close to “*Corynebacterium aquaticum*” (Dorofeeva et al., 1999). All the above-mentioned bacteria were described as members of the new genus *Leifsonia* (Evtushenko et al., 2000). About that time, Suzuki et al. proposed two other species of this genus, *Leifsonia naganoensis* and *Leifsonia shinshuensis* (Suzuki et al., 1999; Suzuki et al., 2000). The authors also proposed to reclassify *Leifsonia xyli* subsp. *cynodontis* as *Leifsonia cynodontis*, since the type strain of *Leifsonia xyli* subsp. *xyli* is no longer available and this subspecies automatically lost its taxo-

nomic status (Suzuki et al., 1999). However, bacteria of this group exist in nature, they are of importance as a cause of sugarcane stunting disease, and the taxon may be restored in the future, with proposal of the neotype strain. The difference between *Leifsonia xyli* subsp. *cynodontis* 16S rDNA sequence and that of *Leifsonia xyli* subsp. *xyli*, which is about the same level as that found between some other species of the genus (Lee et al., 1997b; Fig. 1), as well as their significant difference in 16S–23S internal transcribed spacer (ITS) sequences (Fegan et al., 1998; Pan et al., 1998), suggests that strains of *Leifsonia xyli* subsp. *xyli* may represent a separate species.

Phylogeny

Members of the genus *Leifsonia* form a tight (100% bootstrap confidence) phylogenetic cluster within the radiation of bacteria comprising the family Microbacteriaceae (Fig. 1).

Taxonomy

The genus *Leifsonia* currently harbors five species and two subspecies:

Leifsonia aquatica (ex Leifson, 1962), *Leifsonia xyli* subsp. *xyli* (Davis et al., 1984b), *Leifsonia xyli* subsp. *cynodontis* (Davis et al., 1984b), *Leifsonia poae* (Evtushenko et al., 2000), *Leifsonia naganoensis* and *Leifsonia shinshuensis* (Suzuki et al., 2000).

Organisms of the genus *Leifsonia* usually form yellow, yellowish-white, white or brownish-white colonies, which are circular, somewhat convex, glistening, opaque, and butyrous. Cells are non-sporeforming, irregular rods, usually fragmenting into shorter rods or coccoid elements. Filaments and primary branching occur in young cultures of some species. Organisms are usually motile, mesophilic, obligately aerobic, and catalase positive. Oxidase test is variable among species. Cell wall peptidoglycan is [L-DAB]D-Glu-D-DAB, B2γ type (Schleifer and Kandler, 1972); both isomers, L-DAB and D-DAB, are usually present in almost equal proportion. The muramic acid is acetylated. The major menaquinones are MK-11 and MK-10 or MK-11 and MK-12. Cell wall sugars consist of a predominant amount of rhamnose and minor amounts of glucose, galactose, and mannose; some species contain fucose. Cell wall teichoic acids and mycolic acids are not present. The principal phospholipids are phosphatidylglycerol and diphosphatidylglycerol. Among the fatty acids, *anteiso*-15:0, *anteiso*-17:0 and *iso*-16:0 predominate. Concentrations of polyamines are low; putrescine is the predominant compound. The DNA G+C content is 66.0–71 mol%. This description is based on the data

of Leifson (1962), Fiedler and Kandler (1973a), Yamada et al. (1976), Collins et al. (1979), Collins and Jones (1980a), Döpfer et al. (1982), Davis et al. (1984b), Altenburger et al. (1997), Sasaki et al. (1998), Suzuki et al. (1999), and Evtushenko et al. (2000).

The species differentiation is based on growth, morphological and physiological characteristics, cell wall sugar composition, and menaquinone pattern (see subsection Identification in this Chapter).

Habitat and Phytopathogenicity

Bacteria of the genus *Leifsonia* occur in different environments. The natural habitats of *Leifsonia xyli* and *Leifsonia poae* are plants, where they occur as plant pathogens or saprophytes. *Leifsonia aquatica* has been isolated from distilled water storage tanks and from natural fresh water (Leifson, 1962). Later, representatives of the genus were revealed in bacterioplankton in the Western Mediterranean Sea, at a depth of 80 m (Fritz, 2000). The species *Leifsonia naganoensis*, *Leifsonia shinshuensis* (Suzuki et al., 1999), and some other unidentified organisms of this genus were isolated from soil (Furlong et al., 2002; Jansen et al., 2002; Yanagi et al., 2000).

RATOON STUNTING DISEASE CAUSED BY *LEIFSONIA XYLI* *Leifsonia xyli* subsp. *xyli* invades plant vascular systems, causing ratoon stunting disease in sugarcane (*Saccharum officinarum* L.) in most sugarcane-growing areas of the world (Steindl, 1961; Davis et al., 1984b; Gillaspie and Teackle, 1989). *Leifsonia xyli* subsp. *cynodontis* occurs in Bermuda grass, *Cynodon dactylon* (L.) Pers, and was experimentally shown to cause a disease that does not manifest naturally in this plant (Davis et al., 1980). *Leifsonia xyli* subsp. *xyli* and *Leifsonia xyli* subsp. *cynodontis* are pathogenically distinct, and each induces symptoms in its natural host but not in natural hosts of the other bacterium or in most other plants; each pathogen has been found in nature only in the host in which it was first discovered (Davis et al., 1980; Davis et al., 1984b; Gillaspie and Teackle, 1989). However, both bacteria may inhabit and multiply in the xylem vessels of both hosts and other plants without producing disease symptoms (Steindl, 1961; Davis et al., 1984b; Kostka et al., 1988; Fahey et al., 1991). *Leifsonia xyli* subsp. *xyli* is experimentally transmissible to several gramineous hosts, most of which remain symptomless (Steindl, 1961). The other subspecies, *Leifsonia xyli* subsp. *cynodontis*, or its recombinant with the crystal protein gene of *Bacillus thuringiensis* subsp. *kurstaki*, artificially colonizes more than 80 plant species of 26 families (Kostka et al., 1988; Fahey et al., 1991).

Host plants infected by *Leifsonia xyli* initiate slower growth, look stunted, and may have fewer and thinner stalks, but they show no other external diagnostic symptoms. If plenty of water is available, infected plants may show no stunting and no loss in yield. But infected plants often show internal symptoms. Very young shoots of sugarcane have pinkish discoloration just below the meristematic area of the shoot, above its attachment to the seed piece. In mature canes, symptoms appear as discoloration of individual vascular bundles at the nodes. The pathogen survives in the infected plants and propagative materials such as seeds. The bacteria are also spread by cutting knives and by cultivation and harvesting equipment. They are spread to different countries through infected sugarcane germplasm (Davis et al., 1980).

OCCURRENCE OF OTHER PLANT-ASSOCIATED BACTERIA OF THE GENUS *LEIFSONIA* Strains of *Leifsonia poae* were isolated along with other bacteria from surface-sterilized *Poa annua* root galls induced by the grass root-gall nematode *Subanguina radiculicola* (Evtushenko et al., 2000). There is no evidence of whether this species is a plant pathogen or a root endophyte. Also, no direct relationship between *Leifsonia poae* and the nematode *Subanguina radiculicola* has been deduced.

Nevertheless, the nematode may play a role in bacterial invasion. Plant parasitic nematodes, penetrating roots in the growing zone, a region also preferably colonized by saprophytic bacteria (Grundler and Wyss, 1995), may create wounds which serve as avenues of entry for the endophytic bacteria. In addition, leakage of plant nutrients supports a higher external population of bacteria, thus facilitating a bigger potential source of endophytic colonizers (Hallmann et al., 1997). *Subanguina radiculicola* might also be a nematode vector of *Leifsonia poae* similar to the case described for the *Rathayibacter-Anguina* associations (Price et al., 1979; Riley and Ophel, 1992). Other strains of the genus *Leifsonia* were found in the above-ground parts of grasses without visible nematode infestation (L. I. Evtushenko et al., unpublished observation).

CLINICAL BACTERIA THAT MIGHT BELONG TO THE GENUS *LEIFSONIA* Some strains phenotypically resembling *Leifsonia aquatica* ("*Corynebacterium aquaticum*") were reported to be an agent of meningitis (Beckwith et al., 1986), bacteremia (Kaplan and Israel, 1988; Fischer et al., 1994; Moore and Norton, 1995; Vasseur et al., 1998), urinary tract infections (Tendler and Bottone, 1989), wound infection (Larsson et al., 1996),

and continuous ambulatory peritoneal peritonitis (Morris et al., 1986; Casella et al., 1988; Kwon and Lee, 1997). As no data on 16S rDNA sequences or chemotaxonomic characteristics of most such bacteria are available, their taxonomic position remains unclear. Moreover, some clinical bacteria labelled "*Corynebacterium aquaticum*" were shown to be actually *Microbacterium* spp. (Funke et al., 1994; Grove et al., 1999).

Isolation

ISOLATION OF FAST-GROWING SAPROPHYTIC BACTERIA OF THE GENUS *LEIFSONIA* The fast-growing saprophytic organisms of *Leifsonia* can be successfully isolated from plants, soil and other environments on CB agar, R agar (Yamada and Komagata, 1972a), and some related media by the dilution plating technique. For isolation of *Leifsonia aquatica*, the medium originally developed for the culture of *Caulobacter* (peptone, 3 g; yeast extract, 1 g; K_2HPO_4 , 1 g; agar, 15 g; water, 1 liter; pH 7.1) may be used (Leifson, 1962). Taking into account that *Leifsonia aquatica* is resistant to many antibiotics (Evtushenko et al., 2000), some of them, e.g., chloramphenicol ($10 \mu\text{g}\cdot\text{ml}^{-1}$), may be added to the agar medium to reduce development of many other bacteria. *Leifsonia poae* can be isolated from root galls induced by the root-gall nematode *Subanguina radiculicola* by the following procedure.

Galls inhabited with bacteria are washed, sterilized by 75% (v/v) ethanol for 1 min, dried and pre-incubated in sterile tap water at 24°C for 2 h. Then, galls are cut into pieces, added to 2 ml of NaCl solution at a concentration of 0.85% (w/v), and ground using a pestle. KOH solution may be added to this ground gall suspension to inhibit most Gram-negative bacteria. One drop of this suspension is plated onto CB agar and incubated at room temperature (18–24°C).

Different media based on glucose, peptone and yeast extract are appropriate for cultivation of the rapidly growing organisms of the genus *Leifsonia* (Suzuki et al., 1999; Evtushenko et al., 2000).

ISOLATION AND CULTIVATION OF *LEIFSONIA Xyli*

Certain general rules of isolation of plant pathogens should be followed in the isolation of slowly growing plant pathogens of the genus *Leifsonia* from diseased plants (see the section The Genus *Clavibacter* in this Chapter). The choice of suitable diseased material is of primary importance. The xylem-inhabiting bacteria can be isolated from affected vascular bundles at the nodes, which are usually inhabited by bacteria in the infected plant. Under the microscope, affected bundles appear plugged with bacteria contained in a colored gummy substance. The complex SC

medium (Davis et al., 1980) may be suitable for isolation of both *Leifsonia xyli* subsp. *xyli* and *Leifsonia xyli* subsp. *cynodontis* (Davis et al., 1984b). If this or other nonselective media are used, successful isolation of these two pathogens requires surface sterilization of plant material and other precautions to avoid or reduce the growth of saprophytes (Vidaver and Davis, 1988; Collins and Bradbury, 1992). For isolation of *Leifsonia xyli* subsp. *cynodontis*, a selective complex SCMS medium was developed (Davis and Augustin, 1984a). The SCMS medium is based on SC medium, which is supplemented with the following antibiotics: cycloheximide, 50 mg; 3-hydroxy-5-methylisoxazole (hymexazole), 35 mg; colistin methanesulfonate, 10 mg; and polymyxin B sulfate, 50 mg. The antibiotics are dissolved in 10 ml of water, filter sterilized, and added to 1 liter of molten SC agar at 50°C. Visible colonies appear within 7–14 d on this medium, which are round, convex, entire, and nonpigmented or pale yellow. This medium may also be suitable for isolation of its close relative *Leifsonia xyli* subsp. *xyli* (Collins and Bradbury, 1992).

SC medium is used for growing of *Leifsonia xyli* subsp. *cynodontis* and *Leifsonia xyli* subsp. *xyli* (Davis et al., 1984b). Extracts of Bermuda grass and maize, as well as xylem fluid collected from maize plants, enhance the growth of *Leifsonia xyli* subsp. *cynodontis* (Haapalainen et al., 2000). The growth was enhanced even with 1% (v/v) maize xylem sap in a rich culture medium, giving both an increased growth rate and a higher stationary phase cell density (Haapalainen et al., 2000).

SC medium (Davis et al., 1980)

Cornmeal agar	17 g
Papaic digest of soy meal (or phytone peptone or soytone)	8 g
K_2HPO_4	1 g
KH_2PO_4	1 g
$MgSO_4 \cdot 7H_2O$	0.2 g
Water	1 liter
Bovine hemin chloride	15 mg
Bovine serum albumin (20% solution), fraction V	2 g
Glucose (50% solution)	0.5 g
Cysteine (10% solution)	1 g

The 15 mg of bovine hemin chloride is 15 ml of 0.1% bovine hemin chloride in 0.05N NaOH. The bovine serum albumin (20%), glucose (50%) and cysteine (10%) solutions should be filter sterilized and then 10, 1 and 10 ml, respectively, added to the sterilized molten medium at 50°C. The pH is then adjusted to 6.6.

Data from Davis et al. (1984b), Suzuki et al. (1999), and Evtushenko et al. (2000).

menaquinones MK-11, 10 or MK-11, 12 are the most important phenotypical characteristics allowing the preliminary affiliation of a new mesophilic isolate to the genus *Leifsonia*. However, as new undescribed genera with the same or close characteristics may exist in nature, and weakly motile isolates of *Leifsonia* spp. might be confused with some *Agromyces* species or some others also having DAB in the cell wall (Table 1), at least partial 16S rDNA nucleotide sequencing or restriction analysis of amplified 16S rDNA (Lee et al., 1997b) is necessary to confirm the generic affiliation of the isolate.

SPECIES LEVEL The phenotypic properties given in Table 8 allow affiliation of a fast-growing strain of the genus *Leifsonia* belonging to the species *Leifsonia aquatica*, *Leifsonia naganoensis*, *Leifsonia shinshuensis* and *Leifsonia poae*. Colony color, cell size, menaquinone composition, G+C content of DNA, the presence of fucose in the cell wall, growth in 5% NaCl, and some other physiological features are valuable identifying traits.

The slow-growing plant pathogenic bacteria are relatively easily identified as *Leifsonia xyli* subsp. *xyli* or *Leifsonia xyli* subsp. *cynodontis* at

isolation from sugarcane or Bermuda grass with the typical symptoms of stunting disease. It is usually sufficient to reveal slow-growing, thin, elongated Gram-positive rods showing a tendency to coryneform morphology (Vidaver and Davis, 1988). 16S-23S ITS spacer sequence analysis (Fegan et al., 1998; Pan et al., 1998) is extremely useful for unambiguous identification of *Leifsonia xyli* subsp. *xyli* and *Leifsonia xyli* subsp. *cynodontis*. Some physiological properties (Table 8), cellular protein profiles (Davis et al., 1984b) and 16S rDNA-RFLP patterns (Lee et al., 1997b) are additional helpful identifying traits. Confirmation of identity (and virulence) of pathogens can also be achieved by inoculation of bacteria into a healthy host plant. However, direct testing of virulence is time-consuming and it is often difficult to determine because plant infections are symptomless.

DETECTION OF *LEIFSONIA XYLI* SUBSP. *XYLI*

For practical purposes, *Leifsonia xyli* subsp. *xyli* can be detected by using microscopic (Steindl, 1976) and DNA-based approaches (Fegan et al., 1998; Pan et al., 1998) or immunological techniques (Gillaspie and Teackle, 1989; Shine and Comstock, 1993).

DNA-based methods are widely used for diagnosis. This approach is very helpful when symptomless infection or stunting is caused by some other biotic and abiotic factors. The PCR protocols for sensitive and specific detection of *Leifsonia xyli* based on 16S–23S ITS spacer sequences have been reported (Fegan et al., 1998; Pan et al., 1998). The method was successfully applied to the detection of *Leifsonia xyli* subsp. *xyli* in fibrovascular fluid extracted from sugarcane and was sensitive to approximately 22 cells per PCR assay (Fegan et al., 1998). A multiplex PCR test was developed to differentiate this bacterium from *Leifsonia xyli* subsp. *cynodontis* in a single PCR assay (Fegan et al., 1998). *Leifsonia xyli* subsp. *xyli* can also be detected by DNA hybridization using the fragments of genomic DNA as specific hybridization probes, although weak cross-hybridization may also occur with *Leifsonia xyli* subsp. *cynodontis* (Chung et al., 1994).

Immunological techniques, in particular, tissue immunoblotting, are widely used for diagnosis (Gillaspie and Teackle, 1989; Shine and Comstock, 1993). However, they are usually effective in detecting of *Leifsonia xyli* subsp. *xyli* later in the growing season when the bacterium is present at a high titer; these methods can be unreliable in early to mid-season, when a management decision must be made about which stalks are to be used as the seed cane for the next crop cycle (Pan et al., 1998). In addition, crossreactivity of polyclonal antisera often reduces the specificity of identification (Shine and Comstock, 1993).

Applications and Properties

Owing to low virulence of *Leifsonia xyli* subsp. *cynodontis* and its ability to be artificially transferred into numerous host plants, use of this genetically engineered bacterium for plant protection from disease and insect damage seems promising (Metzler et al., 1997). The engineered bacteria producing beneficial proteins in plants can be used instead of transforming the plant genome. *Leifsonia xyli* subsp. *cynodontis* was modified to produce the crystal protein of *Bacillus thuringiensis* subsp. *kurstaki* and used to protect maize from the European corn borer (*Ostrinia nubilalis*; Dimock et al., 1988; Lampel et al., 1994). Although no increase in the yield was registered at field testing, the considerable protection of maize was observed (Tomasino et al., 1995). The genetically transformed *Leifsonia xyli* subsp. *cynodontis* was also claimed to synthesize and deliver a bioactive compound (antigen, enzyme, hormone, etc.) to animals. The microorganism was cultured to produce this compound in plants, which when eaten by the

animal could induce a therapeutic, biochemical, or immunological response (Koprowski et al., 1997). Several procedures and components useful for genetic manipulation of *Leifsonia xyli* subsp. *cynodontis* were developed and elaborated (Metzler et al., 1992; Metzler et al., 1997; Taylor et al., 1993; Uratani et al., 1995; Haapalainen et al., 1996; Haapalainen et al., 1998; Brumbley et al., 2002).

A new type of glycolipid was obtained from strains S361 and S365, identified as *Leifsonia aquatica* (“*Corynebacterium aquaticum*”; Yanagi et al., 2000). A glycolipid from strain S365 (FERM P-17163) has anti-active oxygen disturbance and cell proliferation activities and was claimed to repair cell membranes damaged by active oxygen (Matsufuji et al., 2000). In a cell extract of *Leifsonia aquatica* (“*Corynebacterium aquaticum*”) M-13, a new enzyme, levodione reductase (an alcohol dehydrogenase/ reductase), was found (Wada et al., 1999; Yoshisumi et al., 2001). This enzyme catalyzed regio- and stereoselective reduction of levodione to actinol and was highly activated by monovalent cations.

The Genus *Leucobacter*

The genus *Leucobacter* with the type species *Leucobacter komagatae* (Takeuchi et al., 1996) was described as an aerobic, nonsporulating rod-shaped organism with an unusual cell wall peptidoglycan containing γ -aminobutyric acid (GABA). Although this compound has been found in every class of living organism, including bacteria, it has not been reported to constitute a major component of the peptidoglycan in bacteria except for *Leucobacter*. GABA is the major inhibitory neurotransmitter in the central nervous system of invertebrates and vertebrates and causes depressant actions in the brain (Turner and Whittle, 1983; Eldefrawi and Eldefrawi, 1987). The role of GABA in the microorganisms, which lack nervous systems, is unclear. A GABA uptake system with binding characteristics like those of the GABA brain receptor is present in *Pseudomonas fluorescens* (Guthrie et al., 1989) and accumulation of GABA in growing cultures is shown to occur by means of an active transport system in *Saccharomyces cerevisiae* (McKelvey et al., 1990).

Phylogeny

The phylogenetic dendrogram (Fig. 1) shows that *Leucobacter komagatae* IFO 15245^T represents a distinct lineage within the radiation of Microbacteriaceae.

Taxonomy

Cells of *Leucobacter komagatae* IFO 15245^T are Gram-positive, nonsporulating, nonmotile, irregular rods that are 0.2–0.3 µm wide and 1.0–1.5 µm long. The optimal temperature for growth is 25°C; no growth occurs at 37 or 4°C. Growth on peptone-yeast agar gives usually low convex, circular, rough, opaque and whitish-brown colonies. Catalase is produced, but oxidase test is negative. The amino acids of the cell wall peptidoglycan are L-alanine, D-glutamic acid, L-DAB, glycine, and an unusual amino acid, GABA; the molar ratio of these compounds was 1.90: 1.00: 0.85: 0.89: 0.72. The acyl type of the cell wall is acetyl. Galactose and glucose are present in the cell wall. The major isoprenoid quinone is menaquinone MK-11. Mycolic acids are not present. The major cellular fatty acids are *anteiso*-15:0, *iso*-16:0 and *anteiso*-17:0. Diphosphatidylglycerol, phosphatidylglycerol, and one unknown glycolipid are present. The G+C content of the DNA is 66 mol%.

The phenotypic properties characteristic of the species are outlined in the subsection Identification in this Chapter.

Habitat

Little is known about the natural habitats of members of the genus *Leucobacter*. The type strain *Leucobacter komagatae* IFO 15245^T on which the description of the genus was based has been isolated as a contaminant in an L-drying ampoule labelled as “*Pseudomonas riboflavina*” IFO 13584, which was later re-identified as *Devosia riboflavina* (Nakagawa et al., 1996). The ampoule was made in 1973 and maintained in the Institute for Fermentation, Osaka. On the basis of 16S rRNA gene sequence analysis, other isolates have been found to be in close phylogenetic relationship to the genus *Leucobacter*. Strain WSP-3 (AF323267) was isolated from a microbial community oxidizing inorganic sulfide and mercaptans (Duncan et al., 2001), the glacial ice bacterium SB12K-2-1 (AF479358) was recovered from 12,000 year-old glacial ice from Sajama, Bolivia (Christner, 2002), and two bacteria were isolated from a bioreactor designed for treatment of gray water (O. Malseva, personal communication) and from an environmental sample (AB012594; Uemori, 1999).

Identification

The most striking phenotypic characteristic which differentiates *Leucobacter komagatae* from 11 genera of the family Microbacteriaceae that have DAB-based cell wall peptidoglycans is the presence of GABA in the cell wall (Table 1). Table 9 shows the phenotypic characteristics

differentiating the genus *Leucobacter* from the other seven genera, members of which contain L-DAB as major diamino acids in their cell walls like *Leucobacter*. In addition to GABA in the cell wall, the genus *Leucobacter* can be discriminated from these genera by the pigmentation, morphology, optimal growth temperature, menaquinone type, mol% G+C content of DNA, and cell wall sugars. Rhamnose is the major sugar component of the cell wall of all the strains belonging to these genera except for *Agromyces cerinus* subsp. *nitratius*, whereas rhamnose is not found in the cell wall of *Leucobacter komagatae*, its major cell wall sugars being galactose and glucose. The optimal temperature for growth readily separates members of *Leucobacter* from those of *Cryobacterium* and *Subtercola*.

In addition to the characteristics given above and listed in the subsection Taxonomy in this Chapter, the following properties may be useful in assigning a bacterial isolate to *Leucobacter komagatae*: ability to produce urease and hydrogen sulfide; positive methyl red test; negative oxidase, nitrate reductase and Voges-Proskauer reactions; the ability to utilize acetate, D- and L-lactate, malate, succinate, propionate, oxalate, and hippurate; and ability to hydrolyze Tween 20, 40, 60, and 80, and urea. Gelatin, starch, and esculin are not hydrolyzed. Growth occurs in the presence of 5.0% NaCl and at pH 10.0, but not pH 5.0.

The Genus *Microbacterium*

The genus *Microbacterium*, the type genus of the family Microbacteriaceae, was proposed by Orla-Jensen (1919) for Gram-positive, nonspore-forming, rod-shaped bacteria isolated during studies on lactic acid-producing bacteria. Currently, the genus *Microbacterium* harbors 33 species listed in Table 10.

Members of the genus *Microbacterium* were characterized largely by their marked heat resistance, presence in dairies, and production of small amounts of L(+) lactic acid from glucose (Doetsch, 1957; Robinson, 1966a). Four species, *Microbacterium lacticum*, “*Microbacterium flavum*,” “*Microbacterium mesentericum*” and “*Microbacterium liquefaciens*” (Orla-Jensen, 1919), were originally included in this genus, while two species, “*Microbacterium thermosphactum*” (McLean and Sulzbacher, 1953) and “*Microbacterium ammoniaphilum*” (Abe et al., 1967), were added later. Subsequent studies showed that the genus *Microbacterium* was heterogeneous. It was revealed that “*M. flavum*,” “*M. ammoniaphilum*” and “*M. mesentericum*” are authentic corynebacteria (Keddie et al., 1966; Robinson, 1966b; Rogosa and Keddie, 1974;

Table 9. Diagnostic characteristics of *Leucobacter komagatae* and the genera having L-DAB in the peptidoglycan.

Barksdale et al., 1979; Collins et al., 1982b), while “*M. thermosphactum*” was reclassified as *Brochothrix thermosphacta* (Sneath and Jones, 1976). “*Microbacterium liquefaciens*,” on the other hand, was considered by many investigators to be merely a gelatin-liquefying variety of *Microbacterium lacticum* (Doetsch and Rakosky, 1950; Jayne-Williams and Skerman, 1966). However, *Microbacterium lacticum* contained lysine as cell wall diamino acid (Keddie et al., 1966; Robinson, 1966b), while “*M. liquefaciens*” had ornithine. “*Microbacterium liquefaciens*” was subsequently reclassified in the new genus *Aureobacterium* as *Aureobacterium liquefaciens* (Collins et al., 1983c).

As a result of systematic chemotaxonomic investigations, the genus *Microbacterium* was defined largely in chemical terms and was thus restricted to those organisms which contained a group B type peptidoglycan based upon L-lysine, predominantly methyl-branched fatty acids, long unsaturated menaquinones (MK-10 to MK-12), and a G+C content of 69–75 mol% (Collins et al., 1983d). The genus *Microbacterium* included six species, viz. *Microbacterium lacticum* (the type species; Orla-Jensen, 1919), *Microbacterium arborescens* (Imai et al., 1984), *Microbacterium aurum*, *Microbacterium dextranolyticum* (Yokota et al., 1993b), *Microbacterium imperiale* and *Microbacterium laevaniformans* (Collins et al., 1983d). On the other hand, the genus *Aureobacterium* including six species was proposed by Collins et al. (1983c) to accommodate organisms which contained a group B type peptidoglycan based upon D-ornithine, predominantly methyl-branched fatty acids, long unsaturated menaquinones (MK-10 to MK-12), and a G+C content of 69–75 mol% (Collins et al., 1983c). Later, Yokota et al. (1993a) and Funke et al. (1998) added seven and one species, respectively.

Thus, the genera *Microbacterium* and *Aureobacterium* were separated primarily on the basis of the cell wall peptidoglycan: B1-type peptidoglycan with an L-diamino acid, L-lysine, was typical of the genus *Microbacterium*, and B2-type peptidoglycan with a D-diamino acid, D-ornithine, was characteristic of the *Aureobacterium* species (Schleifer, 1970; Schleifer and Kandler, 1972; Yokota et al., 1993a). However, in other chemotaxonomic features, the organisms of the two genera exhibited very similar profiles, and a comparative 16S rDNA sequence analysis of members of these genera indicated that they were phylogenetically intermixed within a single monophyletic group (Rainey et al., 1994; Takeuchi and Yokota, 1994). The high phylogenetic similarity and the close relationship in physiological and chemotaxonomic features other than the diamino acid in the cell wall provided evidence that the genera *Aureobacterium*

and *Microbacterium* should be unified (Takeuchi and Hatano, 1998b).

The history and origin of current *Microbacterium* species are outlined in the Table 10. As shown, 11 of 33 species, including the type species *Microbacterium lacticum*, have been assigned to the genus *Microbacterium* in their original descriptions, while the other species were initially dispersed among different genera. *Microbacterium esteraromaticum* was originally described as “*Bacterium esteraromaticum*” (Omeliński, 1923) and later re-allocated to the genus *Flavobacterium* as *Flavobacterium esteraromaticum* (Bergey et al., 1930; Weeks, 1974). “*Flavobacterium suaveolens*” (Soppeland, 1924; Bergey and Breed, 1948; Weeks, 1974) resembled *F. esteraromaticum* chemotaxonomically (Takeuchi and Yokota, 1991), and both type strains showed high DNA-DNA hybridization values (Yokota et al., 1993a), leading to the description of *Aureobacterium esteraromaticum*. *Microbacterium saperdae* and *Microbacterium testaceum* were originally assigned to the genus *Brevibacterium* as *Brevibacterium saperdae* (Lysenko, 1959) and *Brevibacterium testaceum* (Komagata and Iizuka, 1964), respectively, and later transferred into the newly established genus *Curtobacterium* by Yamada and Komagata (1972b). Subsequent chemotaxonomic investigations revealed that *B. saperdae* and *B. testaceum* differed from curtobacteria and they were reclassified as members of *Aureobacterium* (Collins et al., 1983c).

Phylogeny

The genus *Microbacterium* accommodates microorganisms with a B group peptidoglycan containing lysine or ornithine, displaying four variations of the peptidoglycan type. In this respect the genus is unique, as most other actinomycete genera are homogeneous with respect to peptidoglycan type. Nevertheless, microbacteria with different peptidoglycans formed a monophyletic cluster on the basis of 16S rRNA gene sequence analysis (Rainey et al., 1994; Takeuchi and Yokota, 1994; Takeuchi and Hatano, 1998b; Brennan et al., 2001), and the phylogenetic relatedness of *Microbacterium* species does not match differences in the configuration of diamino acids in the interpeptide bridge (peptidoglycan type B1 or B2) or in the amino acid at position 3 of the peptide unit in the peptidoglycan (peptidoglycan type B1a/B1b or B2a/B2b). The following unique nucleotides of 16S rRNA gene were revealed for all strains of the genus *Microbacterium*: G at position 232 (*Escherichia coli* numbering; Brosius et al., 1978), U at position 279, A at position 780, U-A base pair at position 838–856, and A-U base pair

at position 929–1386 (Takeuchi and Hatano, 1998b).

Taxonomy

The current genus *Microbacterium* harbors 33 species (Collins et al., 1983c; Imai et al., 1984; Yokota et al., 1993a; Yokota et al., 1993b; Funke et al., 1998; Takeuchi and Hatano, 1998b; Takeuchi and Hatano, 1998a; Matsuyama et al., 1999; Schumann et al., 1999; Behrendt et al., 2001; Brennan et al., 2001; Zlamala et al. 2002b), listed in Table 10.

Members of the genus have white, whitish yellow, yellow or orange colonies. In young cultures, cells are small irregular short slender rods (ca. 0.4–0.8 µm in diameter and 0.7–4 µm in length) occurring singly or in groups. They become shorter with age (3–7 d), a proportion may be coccoid, but a marked rod-coccus growth cycle does not occur. Some cells are arranged at angles to each other to give V-forms. Primary branching is uncommon. Cells are Gram positive, but older cultures may fail to retain the Gram stain. Cells do not form endospores and may be nonmotile or motile by lateral flagella. Cells are chemoorganotrophic and catalase positive. Metabolism is primarily respiratory but may also be fermentative. Microbacteria may show weak oxidative acid production from some carbohydrates.

The cell wall peptidoglycan contains L-lysine as the diamino acid, type B1α (*Microbacterium dextranolyticum*, *Microbacterium hominis*, *Microbacterium lacticum* and *Microbacterium laevaniformans*; Schleifer and Kandler, 1972; Collins et al., 1983d; Yokota et al., 1993b; Takeuchi and Hatano, 1998a) or type B1b (*Microbacterium arborescens*, *Microbacterium aurum* and *Microbacterium imperiale*; Schleifer and Kandler, 1972; Imai et al., 1984; Yokota et al., 1993b), or has D-ornithine as the diamino acid, type B2a (*Microbacterium keratanolyticum* [Yokota et al., 1993a] and *Microbacterium resistens* [Funke et al., 1998; Behrendt et al., 2001]) or type B2β (all other species; Schleifer and Kandler, 1972; Yokota et al., 1993a; Yokota et al., 1993b; Takeuchi and Hatano, 1998b; Takeuchi and Hatano, 1998a; Behrendt et al., 2001; Table 11). The presence of 3-threo-hydroxyglutamic acid in the peptidoglycan, which particularly substitutes glutamic acid at position 2 of the peptide subunit, is typical of microbacteria.

Microbacterium schleiferi contains hydroxyornithine as a diamino acid in its cell wall peptidoglycan (Schleifer et al., 1983), variation B2b of Schleifer and Kandler (Schleifer and Kandler, 1972; Yokota et al., 1993a), and the molar ratio of ornithine plus hydroxyornithine to homoserine to glutamate plus hydroxyglutamate to glycine to alanine to lysine is 1:1:1:2:1:0.4. The

glycan moiety of the cell wall contains both *N*-glycolyl and *N*-acetyl residues (Uchida and Aida, 1977). Arabinogalactan is not produced. A variety of sugars (e.g., galactose, glucose, rhamnose, 6-deoxytalose, fucose and xylose) occur in the cell walls; composition varies with strain and species (Keddie and Cure, 1977; Yokota et al., 1993a; Yokota et al., 1993b; Takeuchi and Hatano, 1998b; Takeuchi and Hatano, 1998a). Mycolic acids are not produced. Menaquinones are the sole respiratory quinones. All strains contain very long, unsaturated menaquinones, such as MK-11, MK-12 and MK-13, while MK-10 and MK-14 are minor components (Collins et al., 1980b; Collins et al., 1983c; Collins et al., 1983d; Yokota et al., 1993a; Yokota et al., 1993b). The long-chain cellular fatty acids are mainly of the *anteiso*- and *iso*-methyl branched types, with *anteiso*-15:0, *iso*-16:0 and *anteiso*-17:0 acids predominating. All microbacteria contain diphosphatidylglycerol and phosphatidylglycerol as their major polar lipids, and minor amounts of monomannosyldiacylglycerol, phosphoglycolipid and unidentified glycolipids may also occur (Collins et al., 1983c; Collins et al., 1983d). The G+C content is 66–72 mol%.

The phenotypic delineation of 33 *Microbacterium* species is based on some chemotaxonomic features, such as diamino acid in the cell wall, murein type, major menaquinone and cell wall sugars, combined with growth and physiological features (see subsection Identification in this Chapter and Tables 7, 11 and 12).

Habitat

Members of the genus *Microbacterium* are widely distributed in various environments (Table 10) and can be associated with plants, insects and clinical specimens. The examples presented in the Table 10 and outlined below, while not exhaustive, demonstrate the vast diversity of habitats of microbacteria.

Microbacterium lacticum is usually found in milk, powdered milk, cheese, and on dairy equipment, and it is considered to represent a major part of the thermophilic coryneform bacterial population of such sources (Jayne-Williams and Skerman, 1966; Thomas et al., 1967; Gillies, 1971). *Microbacterium liquefaciens* has also been isolated from milk, cheese, dairy products, and dairy equipment (Collins et al., 1983d). Organisms that phenotypically resemble this species are also found in soil (Topping, 1937) and frozen vegetables (Splittstoesser et al., 1967). *Microbacterium halophilum*, *Microbacterium thalassium* and some other strains considered to be new species of the genus *Microbacterium* were isolated from soils in the mangrove rhizosphere in Okinawa, Japan

Table 11. Chemotaxonomic characteristics of the species in the genus *Microbacterium*.

	Species	G+C content (mol %)	Major menaquinone ^a	Cell wall			Fatty acids ^{cd}	Polar lipids ^{cd}

Symbols and abbreviations: +, positive reaction; +w, weakly positive; -, negative; +/-, different results in cited references (Takeuchi and Hatano [1993a; 1993b]); d, reaction differs among strains; ND, not determined; YW, yellow white; O, orange; DO, dull violet with brown; W, white; LX, light yellow; BY, bright yellow; Cr, cream; GEL, gelatin; STA, starch; H₂S, H₂S production; VP, Voges-Proskauer test; ADH, arginine dihydrolase; ARA, arabinose; NAG, N-acetylglucosamine; CIT, citrate; MLT, malate; PAC, phenyl acetate; FUM, fumarate; and GLC, glucose.

^aMost tests for characterizing the biochemical profiles of studied strains were performed by the methods described by Cowan (1974), Behrendt et al. (1999) or Takeuchi and Hatano (1998a). API 20NE (bioMérieux) and the API 50CH gallery using the API CHE suspension medium (bioMérieux) were used to determine physiological and biochemical characteristics of some species. Data from references listed in Table 11.

(Takeuchi and Hatano, 1998a; Takeuchi and Hatano, 1999). In the mangrove forests, complex environments have formed under the influence of tide, the influx of fresh water, and high temperature and humidity in the subtropical and tropical climates. The soils in such environments are muddy and are reported to be anoxic, low in nutrients, and to have higher concentrations of heavy metals and higher salinity than terrestrial soils have (Wakushima et al., 1994). Microbacteria were also revealed in the rhizoplane of oil-seed rape (Kaiser et al., 2001).

Microbacterium foliorum and *Microbacterium phyllosphaerae* were isolated from grasses and the surface litter after mulching the sward (Behrendt et al., 2001). *Microbacterium testaceum*, first isolated from rice paddy mud (Komagata and Iizuka, 1964), was also found among endophytic bacteria, which reside within plant hosts without causing disease symptoms (Zinniel et al., 2002). Elbeltagy et al. (2000) found endophytic microbacteria and corynebacteria along with some other strains in wild and traditionally cultivated rice varieties. Different strains of the genus *Microbacterium*, including *Microbacterium testaceum*, were isolated from plant galls of grass induced by plant parasitic nematodes of the subfamily Anguininae (Evtushenko et al., 1994; L. I. Evtushenko and M. Takeuchi, unpublished observation). However, microbacteria do not seem to be predominant among other coryneform isolates in bacterium-nematode complexes in the galls. They are probably secondary settlers of the galls, descending from the phylloplane or the healthy plant tissue, and have no relationship with nematodes. In contrast, "*Microbacterium nematophilum*" was reported to be the infectious agent of the nematode *Caenorhabditis elegans*, which fortuitously contaminates the nematode (Hodgkin et al., 2000). The bacteria adhere to the cuticle of susceptible nematodes and induce substantial local swelling of the underlying hypodermal tissue. The induced deformation appears to be part of a survival strategy for the bacteria, as *Caenorhabditis elegans* appears to be their predator (Hodgkin et al., 2000). *Microbacterium imperiale* was isolated from alimentary tract of the imperial moth *Eacles imperialis* (Steinhaus, 1941) and *Microbacterium saperdae* was isolated from dead larvae of Elm borer *Saperda caracharias* (Lysenko, 1959). Recently, some microbacteria were isolated as microbial symbionts of Great Barrier Reef sponges (Burja et al., 1999), and they were also found among cellulolytic bacteria inhabiting the gut of the termite *Zootermopsis angusticollis* (Wenzel et al., 2002).

Free-living, aerobic, copiotrophic ultramicrobacteria (Koch, 1996) that passed through a 0.45- μm membrane filter and had a cell volume of less than 0.3 μm^3 were isolated from polluted

urban soil (Iizuka et al., 1998). Microbacteria were revealed in the sea mud of the Mariana Trench (Takami et al., 1997) and in the Western Mediterranean Sea (Fritz, 2000). They were found in 12,000 year-old glacial ice from Sajama, Bolivia (Christner, 2002) and in permafrost sediments recovered from a frozen (annual mean temperature -12°C) late Pliocene layer, 1.8–3 million years old, in East Siberia (Karasev et al., 1998; Kochkina et al., 2001). It is interesting to note that many of the permafrost microbacteria were found in samples containing plant residues and were associated with *Rhodococcus* sp. in the two-member cultures isolated on agar media (Kochkina et al., 2001). Phylogenetic and phenotypic data indicate that some of these strains represent new species of the genus *Microbacterium* (L. I. Evtushenko and M. Takeuchi, unpublished observation). Microbacteria were also recovered from condensation water samples of the Russian space station "Mir" (Kawamura et al., 2001) and in a phosphorus-removing bacterial consortium consisting initially of 18 bacterial strains in a sequence batch reactor under alternating aerobic/anaerobic conditions and without additional carbon sources (Hollender et al., 2002).

CLINICAL MICROBACTERIA Several reports have lately indicated the association of *Microbacterium* spp. (*Aureobacterium* spp.) with diseases (Funke et al., 1997). Microbacterial strains resembling organisms of CDC coryneform groups A-4 and A-5 (Hollis and Weaver, 1981) were recovered from different clinical specimens, mostly blood cultures (Funke et al., 1995). Clinically significant strains, presumptively microbacteria, were isolated from patients with endocarditis (Lifshitz et al., 1991), septicemia (Bizette et al., 1995), catheter-related septicemia (Campbell et al., 1994), exogenous endophthalmitis (Barker et al., 1990), acute myelogenous leukemia (Nolte et al., 1996), and some other diseases. *Microbacterium* sp., along with other microorganisms, were detected by molecular methods in advanced noma lesions, although owing to the limited number of available noma subjects it was impossible to associate specific species with the disease (Paster et al., 2002). Hanscom and Maxwell (1979) experimentally demonstrated that a clinical *Microbacterium* strain fulfilled the Koch-Henle postulates for causing endophthalmitis. Most microbacterial infections were reportedly self-limited (Carlotti et al., 1993; Funke et al., 1997). A case of lethal *Microbacterium* bacteremia in an immunocompromised patient was described by Nolte et al. (1996). Saweljew et al. (1996) reported a case of fatal systemic infection of an immunocompetent patient with *Microbacterium* sp. The mode of transmission of most *Microbacterium*

strains to humans remains to be elucidated, although the central venous catheter was previously proposed to be a source of bacteremia (Campbell et al., 1994; Grove et al., 1999). The documented case of catheter-related *Microbacterium* bacteremia has recently been reported by Lau et al. (2002).

Some clinical strains were identified or found to be new species. The strain *Microbacterium* sp. CDC group A-4 from lung aspirate was described as the new species named "*Microbacterium hominis*," and *Microbacterium* sp. CDC group A-5 from blood was identified as *Microbacterium laevaniformans* (Takeuchi and Hatano, 1998a). Strains from corneal ulcer and blood culture of a patient with acute myelogenous leukemia were described as the new species *Microbacterium resistens* (Funke et al., 1998; Behrendt et al., 2001). *Microbacterium* sp. isolated repeatedly from blood taken through the lumina of a central venous catheter of a patient with multiple myeloma had a 99.5% identity with *Microbacterium liquefaciens*, but there was a slight phenotypic difference from the description of this species (Grove et al., 1999). A bacterium showing 99.4% 16S rDNA sequence similarity to *Microbacterium oxydans* was revealed in both the blood culture and central catheter tip of a patient with chronic myeloid leukemia (Lau et al., 2002).

Isolation and Cultivation

Since most strains of *Microbacterium lacticum* are thermophilic (survive 63°C for 30 min or 72°C for 15 min in skim milk; Abd-el-Malek and Gibson, 1952; Jayne-Williams and Skerman, 1966), the usual procedure for isolating this organism from dairy products involves plating laboratory-pasteurized (63°C for 30 min) samples onto a suitable, nonselective medium. However, the pasteurization step should be omitted if nonthermophilic strains are also to be isolated. A suitable nonselective medium is yeast extract milk agar (YMA; Harrigan and McCance, 1976). Dias and Bhat (1962a) have described an enrichment procedure for the isolation of *Microbacterium laevaniformans* from raw sewage and activated sludge. Bacteria other than *Microbacterium laevaniformans* are, however, also enriched by this method. A good general-purpose medium for the cultivation of most microbacteria is Corynebacterium (CB) agar containing 0.5% glucose, 1% casein-peptone-tryptic digest, 0.5% yeast extract, 0.5% NaCl and 1.5% agar (pH 7.2). Strains should be incubated aerobically at 28–30°C. *Microbacterium terregens* and *Microbacterium flavescens* reportedly have a requirement for the terregens factor (Lochhead and Burton, 1953; Lochhead, 1958), and these

species can be cultivated on a variety of conventional media supplemented with soil extract. A suitable medium is soil extract nutrient agar. However, most microbacteria (including *Microbacterium terregens* and *Microbacterium flavescens*) grow well on peptone-yeast extract (PY) agar medium containing 1% (w/v) peptone, 0.2% yeast extract, 0.2% NaCl, 0.2% MgSO₄ · 7H₂O and 1% agar (pH 7.0) or on CB agar.

Soil Extract Nutrient Agar

Lab-Lemco beef extract	1 g
Yeast extract	2 g
Peptone	5 g
NaCl	5 g
Agar	15 g
Soil extract	1 liter
pH 7.0	

Soil extract is prepared by suspending 500–1000 g of soil in 1 liter of tap water and autoclaving at 121°C for 30 min. Clear supernatant is obtained by filtration or centrifugation.

Identification

A classification system based on phylogenetic clustering and the presence of taxon-specific 16S rDNA/RNA signature nucleotides enables new isolate assignment to the genus *Microbacterium* or even to a certain species group. Cell morphology combined with some chemotaxonomic characteristics, mainly the composition of amino acids of peptidoglycan and major menaquinones, is useful for preliminary identification of novel isolates as microbacteria at the phenotypical level (Tables 1 and 7). Besides the genus *Microbacterium*, only three genera in the family, namely, *Frigoribacterium*, *Mycetocola* and *Oribacterium*, have lysine in their peptidoglycan and two genera, *Curtobacterium* and *Agreia*, contain ornithine. Among the genera with lysine-based peptidoglycan, the *Microbacterium* species are distinguished by the presence of 1 or 2 molecules of lysine and 2 or 3 molecules of glycine in the polymer subunit and the major menaquinones MK-11 and MK-12 (Table 7). Microbacteria with ornithine in the cell wall clearly differ from *Curtobacterium* and *Agreia* in the major menaquinones. They can also be separated from *Agreia* by lacking DAB in the cell wall.

Some chemotaxonomic features (Table 11), such as major menaquinone, murein type, diamino acids, and sugar composition of the cell wall, vary among the *Microbacterium* species and may serve to differentiate individual species from others. It is currently not easy to select growth and physiological characteristics that allow unambiguous identification of *Microbacterium* species. However, some of them (Table 12) combined with the chemotaxonomic properties (Tables 7 and 11) permit new isolates of the

genus *Microbacterium* to be identified at the species level.

Preservation

Various methods for long-term preservation of microorganisms, including freeze-drying, liquid-drying (L-drying), and freezing at -80°C or at -196°C , are suitable for preservation and maintenance of microbacteria and other organisms of the family. L-drying involves vacuum-drying of samples from the liquid state without freezing, and it is known to be useful for the preservation of microorganisms that are sensitive to freeze-drying (Anner, 1970; Imai and Sakane, 1985; Malik, 1990; Sakane et al., 1992). Iijima and Sakane (1973) improved the L-drying method described by Anner (1970). Potassium phosphate (0.1M) buffer, containing 3% monosodium glutamate, 1.5% ribitol and 0.05% cysteine-HCl (pH 7.0), is a useful protective medium for most bacteria. Two additives, ribitol and cysteine-HCl, prevent mutation induced by desiccation (Sakane et al., 1983; Imai and Sakane, 1985).

Most Gram-positive bacteria including microbacteria and other members of the family Microbacteriaceae dried by the L-drying method usually showed a high survival rate, and these dried cultures appeared to have been preserved for a long time. Sakane and Kuroshima (1997), who examined the viabilities of 59 L-dried bacterial cultures stored 21–24 years at 5°C and compared these viabilities with previous estimates, found that the survival rates of L-dried microorganisms stored 16 years at 5°C were unchanged and that the rate after storage for over 20 years could be estimated by an accelerated storage test requiring 2 weeks at 37°C .

Applications and Properties

Some microbacterial strains show interesting biochemical features, and some organisms play important roles in the chemical industry. *Microbacterium arabinogalactanolyticum* produces *a*-arabinofuranosidase (Kotani et al., 1972). *Microbacterium dextranolyticum* synthesizes dextran-*a*-1,2-debranching enzyme (Kobayashi et al., 1978; Mitsuishi et al., 1979; Mitsuishi et al., 1980). *Microbacterium keratanolyticum* produces keratan sulfate endo-*b*-galactosidase (Nakazawa and Suzuki, 1975a; Nakazawa et al., 1975b). *Microbacterium ketosireducens* reduces 2,5-diketo-D-gluconic acid (Takeuchi and Hatano, 1998a). *Microbacterium trichothecenolyticum* was reported to degrade trichothecene mycotoxins (such as T-2 toxin, diacetoxyscirpenol, neosolaniol, nivalenol, and fusarenol-X) produced by various species of

fungi and can occur in agricultural products, including cereals and pulses (Nakayama et al., 1980; Ueno et al., 1983). Consumption of trichothecene-contaminated foods by farm animals and humans leads to mycotoxicosis. Trichothecenes are known to induce hematological disorders such as neutropenia, aplastic anemia, and thrombocytopenia in humans and animals (Froquet et al., 2001). Shafiee et al. (1998) purified, characterized and immobilized an NADPH-dependent enzyme involved in the chiral specific reduction of the keto ester M, an intermediate in the synthesis of an anti-asthma drug, Montelukast, from "*Microbacterium campuquemadoensis*." Asano and Tanetani (1998) found a thermostable phenylalanine dehydrogenase from a mesophilic *Microbacterium* sp. Desaint et al. (2000) isolated the carbofuran-degrading microbacteria from soil, and Chee-Sanford et al. (2001) reported on the diversity of tetracycline resistance genes in a microbacterium (phylogenetically closest to *Microbacterium oxydans*) found in waste lagoons and in groundwater underlying two swine farms. Unusual microbacteria with arsenic (III)-oxidizing and chromate (VI)-reducing activities were found in sewage and tannery waste (Pattanapitpaisal et al., 2001; Mokashi and Paknikar, 2002). *Microbacterium esteraromaticum* is an aroma-producing bacterium (Omelianski, 1923; Soppeland, 1924). *Microbacterium barkeri* shows pectinolytic activity (Dias et al., 1962b). *Microbacterium kitamiense* and *Microbacterium phyllosphaerae* produce insoluble and soluble exopolysaccharides (Matsuyama et al., 1999; Behrendt et al., 2001). *Microbacterium laevaniformans* produces levan from sucrose and raffinose (Dias and Bhat, 1962a). *Microbacterium resistens* is resistant to vancomycin (Funke et al., 1998).

In addition to the 33 discussed species (Table 10) another new species, *Microbacterium paraoxydans* with the type strain CF36 (= CCUG 46601 = DSM 15019), has recently been described (Laffineur et al., 2003) and validated. Representatives of the new species were isolated from the blood of a child with acute lymphoblastic leukemia who was perfused with a central venous catheter. The physiological, chemotaxonomic, and genetic characteristics of *Microbacterium paraoxydans* indicated that this species is closely related to *Microbacterium oxydans*. The G+C content of its DNA is 69.9 mol%.

The Genus *Mycetocola*

The genus *Mycetocola*, with the type species *Mycetocola saprophilus*, was established by Tsukamoto et al. (2001) to accommodate

tolaasin-detoxifying bacteria, which were isolated from the cultivated mushroom *Pleurotus ostreatus*. Tolaasins, pathogenic toxins (Nutkins et al., 1991; Shirata et al., 1995) produced extracellularly by *Pseudomonas tolaasii* Paine, cause brown blotch disease in economically important cultivated mushrooms, *Pleurotus ostreatus* Kummer and *Agaricus bisporus* Singer (Tolaas, 1915; Suyama and Fujii, 1993).

Phylogeny

Phylogenetically (Fig. 1), the type strains of three species of the genus *Mycetocola* form an independent, well-defined (100% bootstrap confidence) cluster that is usually located close to the root of the genus *Microbacterium* branch.

Taxonomy

Members of the genus *Mycetocola* are Gram-positive, nonmotile, irregular rods, 0.2–0.4 μm wide and 2.0–3.5 μm long. Mycelium and endospores are not produced. Growth on peptone-yeast agar gives usually convex, smooth, yellowish-white colonies. Bacteria are obligately aerobic, and no growth occurs in anaerobic conditions. The optimal growth temperature is 25°C, the maximum temperature for growth is 33°C, and no growth occurs at 4°C. Acid is produced from glucose and various other carbohydrates. Catalase is produced, but oxidase is not. All bacteria of this genus are able to detoxify tolaasins produced by *Pseudomonas tolaasii*. Cell wall peptidoglycan contains lysine as the diamino acid, and the muramic acid of the cell wall is an acetyl type. The major isoprenoid quinone is menaquinone MK-10, and small amounts of MK-9 and MK-11 are present. The major fatty acids are *anteiso*-C_{15:0} and *anteiso*-C_{17:0}. The G+C content is 63.9–64.7 mol% (Tsukamoto et al., 2001).

Currently, the genus includes three species, *Mycetocola saprophilus*, *Mycetocola tolaasini-vorans* and *Mycetocola lacteus* (Tsukamoto et al., 2001), which show similar physiological properties. The species differentiation is based on a low DNA-DNA relatedness level, indicating separate genomic species (Wayne et al., 1987), which is consistent with some phenotypical characteristics discussed in the subsection Identification in this Chapter.

Habitat

The data available suggest that the natural habitat of *Mycetocola* is mushrooms. Bacteria of this genus were found to be associated with *Agaricales* mushrooms such as *Pleurotus ostreatus* (Jacq.:Fr) Kummer and *Lepista nuda* (Bull.: Fr.)

Cooke (Tsukamoto et al., 1998; Tsukamoto et al., 2001; Tsukamoto et al., 2002). Some mushrooms undergo blackening by *Pseudomonas tolaasii*, which produces extracellular lipodepsipeptide toxins (i.e., tolaasins; Tolaas, 1915; Suyama and Fujii, 1993) that induce blotch symptoms (Nutkins et al., 1991; Rainey et al., 1993; Shirata et al., 1995; Murata and Magae, 1996; Murata et al., 1998). *Mycetocola* spp. detoxify the tolaasins and suppress the development of the disease (Tsukamoto et al., 1998). *Mycetocola* species are saprophytic but not parasitic or pathogenic to *Pleurotus ostreatus* (Tsukamoto et al., 1998).

Isolation

Bacteria of the genus *Mycetocola* can be found in rotting fruiting bodies of some cultivated or wild *Agaricales* fungi (e.g., *Pleurotus ostreatus* and *Lepista nuda*). For isolation, the potato-semisynthetic agar (PSA; Wakimoto, 1955) and T-PAF medium (Suyama et al., 1995) can be used.

PSA medium (Wakimoto, 1955)

Sucrose	15 g
Peptone	5 g
Ca(NO ₃) ₂ · 4H ₂ O	0.5 g
Na ₂ HPO ₄ · 12H ₂ O	2 g
Decoction of 300 g of potato tuber slices	1 liter
Agar	15 g
pH 7.0	

T-PAF medium is based on *Pseudomonas* agar F (PAF) supplemented with tolaasin (Suyama et al., 1995). Viable cells of *Mycetocola* form yellow colonies, while *Pseudomonas tolaasii* produces distinctive blue colonies on T-PAF and PSA (Suyama et al., 1995; Wakimoto, 1955). The tolaasin-detoxifying *Mycetocola* spp. can also be isolated by using the potato tuber slice method (Shirata et al., 1995). Microorganisms selected as tolaasin-detoxifying strains are cultured aerobically at 28°C in a peptone-yeast (PY) medium containing 10 g of peptone, 2 g of yeast extract, 2 g of NaCl and 2 g of D-glucose in 1 liter of distilled water (pH 7.2) or other media based on peptone, glucose and yeast extract.

Identification

As shown in Tables 1 and 7, only members of three genera in the family Microbacteriaceae, *Frigoribacterium* (Kämpfer et al., 2000), *Okibacterium* (Evtushenko et al., 2002) and *Microbacterium*, along with the genus *Mycetocola*, have lysine in the cell wall. Among them, only *Mycetocola* and *Frigoribacterium* are characterized by presence of lysine as the diamino acid and acetyl-type muramic acid in the peptidoglyc-

can. Bacteria of these two genera can be distinguished by motility, growth temperature, major menaquinone, and fatty acids (including 1,1-dimethyl acetals), and DNA G+C content. In addition, the ability to detoxify tolaasins has not been reported for *Frigoribacterium* and other Microbacteriaceae.

The three species in the genus *Mycetocola* are very similar phylogenetically and physiologically. To assess whether a new isolate belongs to the known species of *Mycetocola* or to a new species, the following characteristics, along with the source of isolation, may be used: catalase reaction is positive, but oxidase, Voges-Proskauer and methyl red tests are negative; nitrate or nitrate is not reduced; hydrogen sulfide, lecithinase, tyrosinase, and urease are not produced; esculin is hydrolyzed, but arbutin, arginine, and casein are not hydrolyzed; no liquefaction of gelatin and production of indole, 3-ketolactose, 2-ketogluconate and levan from sucrose occur; fumarate is used as a sole carbon source, but asparagine is not used as a sole nitrogen and carbon source; benzoate, butyrate, *m*-hydroxybenzoate, malonate, oxalate, propionate, D- and L-tartarate are not utilized; acid is produced from D-cellobiose, dextrin, D-fructose, D-galactose, D-glucose, glycerol, lactose, maltose, D-mannitol, D-mannose, melibiose, D-ribose, salicin, D-sorbitol, sucrose, trehalose or D-xylose, but not from D- and L-arabinose, D-dulcitol, *m*-inositol, inulin, D-raffinose, L-rhamnose, or starch. Growth occurs in peptone water, but not in Corn's solution, Fermi's solution, and Uschinsky's solution. Maceration of potato tubers and hypersensitive reaction in tobacco leaves are not found (Tsukamoto et al., 2001).

To preliminarily assign a novel isolate to one of the known *Mycetocola* species, the following information is helpful: *Mycetocola lacteus* produces acids from both D-melezitose and erythritol and also utilizes both citrate and Tween 80; *Mycetocola tolaasinivorans* does not produce acid from either D-melezitose or erythritol and does not utilize either citrate or Tween 80. *Mycetocola saprophilus* produces acid from D-melezitose but not from erythritol and utilizes citrate but does not hydrolyze Tween 80. DNA-DNA hybridization tests or analyses of other adequate genomic characteristics (Vandamme et al., 1996; Stackebrandt et al., 2000, 2002; Rossello-Mora and Amann, 2001) may be necessary to support species identification.

Applications and Features

Tolaasin produced by *Pseudomonas tolaasii* disrupts cell membranes by forming a voltage-gated ion channel and acts as a biosurfactant, leading

to the cell death of mushroom mycelia (Brodey et al., 1991; Hutchison and Johnstone, 1993). Elimination of contaminants by periodically cleaning facilities with disinfectants such as chlorine and by carefully controlling humidity and temperature during cultivation of mushrooms seems to be effective in controlling the outbreak of disease (Fletcher et al., 1989). Development of efficient biological methods to control disease is important, since, in principle, the use of chemicals or antibiotics should be avoided in mushroom culture. Use of strains of *Mycetocola* could be a unique approach for developing a biocontrol system of cultivated mushrooms, particularly *P. ostreatus*. It is different from the biocontrol system in *Agaricus bisporus* cultivation, where an antagonistic bacterium, i.e., *Pseudomonas fluorescens* (Trevisan) Migula, is allowed to grow on the mushroom casing layer to suppress physically the incoming population of *Pseudomonas tolaasii* (Nair and Fahy, 1972; Nair and Fahy, 1976; Fermor et al., 1991). However, *Pseudomonas fluorescens* is pathogenic to cultivated mushrooms by producing various antifungal agents (Laville et al., 1992; Corbell and Loper, 1995) and is closely related to *Pseudomonas tolaasii* (Thorn and Tsuneda, 1996).

In contrast to *Pseudomonas fluorescens*, strains of *Mycetocola* are saprophytic and markedly reduce the level of tolaasin by live suppressive bacterial cells (Tsukamoto et al., 1998). However, many problems must be solved before the bacterium can be used as a control agent. The major problem is the possibility of side effects of the *Mycetocola* strain on the environment as well as on human health. Another problem is that the effectiveness of *Mycetocola* strains in preventing the development of brown blotch was not as high as the suppression of the tolaasin effect *in vitro*. Reduced disease suppression *in vivo* may be partly due to the decreased population size of strains inoculated on *Pleurotus ostreatus*. This could be attributed to the presence of host components detrimental to the strains or to the limitation of nutrients available to the bacterium on the host mycelia. The suppressive bacterium may be useful in future biocontrol system development and/or the construction of genetically modified edible fungi resistant to the disease caused by *Pseudomonas tolaasii*.

The Genus *Okibacterium*

The genus *Okibacterium* with the single species *Okibacterium fritillariae* was proposed to accommodate aerobic coryneform bacteria isolated from plant seeds (Evtushenko et al., 2002).

Phylogeny

Phylogenetic analysis (Fig. 1) indicated that the strains of the genus *Okibacterium* form a separate phylogenetic branch closely linked to the lineage of the recently proposed genus *Plantibacter* (Behrendt et al., 2002), to which it shows more than 97% 16S rDNA binary sequence similarity.

Taxonomy

Strains of the genus form yellow, circular, and glistening colonies. Cells are irregular nonspore-forming, nonmotile, irregular rods ($0.4\text{--}0.6 \times 0.7\text{--}1.5\text{ }\mu\text{m}$), becoming short rods or cocco-bacillaric cells in old culture. Strains are catalase- and oxidase-positive. Growth occurs at $7\text{--}37^\circ\text{C}$, with the optimum at $24\text{--}26^\circ\text{C}$. The bacteria are characterized by a cell wall peptidoglycan based upon lysine, the glycolyl residue of muramic acid, the major menaquinones MK-10 and MK-11, and a DNA G+C content of 67 mol%. The composition of amino acids in the peptidoglycan (lysine, alanine, glycine, glutamate, homoserine, molar ratio close to 1:1:1:1:0.5) was identical to that determined in *Frigoribacterium faeni* (Kämpfer et al., 2000). Currently, the genus includes one validly described species, *Okibacterium fritillariae* (Evtushenko et al., 2002). The typical characteristics of this species are outlined in the subsection Identification in this Chapter.

Habitat

Little is known about natural habitat of *Okibacterium*. Strains of the species *Okibacterium fritillariae* were isolated from surface-non-sterilized seeds of *Fritillaria ruthenica* Wikstr. and *Clematis recta* L. collected in Prioksko-Terrasny Biosphere Park, Moscow region, Russia. Besides *Okibacterium*, a few bacterial and fungal isolates developed on CB agar from a drop of ground seed suspension (Evtushenko et al., 2002). As determined from the 16S rRNA gene sequence, strain “*Microbacterium* sp.” VA8728_00 (AF306834), isolated recently from central venous catheter of a heart transplantation patient, is a new member of the genus.

Isolation

Okibacterium fritillariae may be isolated from seeds by the following method: the seeds are cut into pieces, added to 1 ml of 0.85% NaCl (w/v) solution, and ground with a pestle, and the suspension is plated onto CB agar and incubated at room temperature ($18\text{--}24^\circ\text{C}$). Other media used for cultivation of aerobic heterotrophic bacteria,

including TS agar (Difco), R agar (Yamada and Komagata, 1972a) and some other media based on glucose, peptone and yeast extract, are also suitable for isolation and growing of *Okibacterium fritillariae*.

Identification

The genus *Okibacterium* can be readily distinguished from its phylogenetic neighbor, the genus *Plantibacter* (Behrendt et al., 2002), and most other genera of the family Microbacteriaceae at the phenotypical level, mainly owing to its lysine-based peptidoglycan and the major menaquinones MK-10 and MK-11 (Table 1). Besides *Okibacterium*, only *Frigoribacterium* (Kämpfer et al., 2000), *Mycetocola* (Tsukamoto et al., 2001) and eight species of *Microbacterium* (Takeuchi and Hatano, 1998b; Takeuchi and Hatano, 1998a; Brennan et al., 2001; Behrendt et al., 2002) possess cell wall peptidoglycans based upon lysine (Table 7). The nonmotile cells, the major menaquinones MK-10, 11, the glycolyl type of muramic acid, and the G+C content of DNA clearly separate *Okibacterium* from *Frigoribacterium*, which has the same composition and molar ratio of the peptidoglycan amino acids. *Okibacteria* can be differentiated from lysine-containing species of *Microbacterium* by the major menaquinones, the G+C contents of DNA, and cell wall sugars. In addition, the composition and molar ratio of peptidoglycan amino acids (lysine, alanine, glycine, glutamate, and homoserine) are different and *threo*-3-hydroxyglutamate is lacking. *Mycetocola* spp. differ from *okibacteria* in cell shape and size and the peptidoglycan composition (the presence of an unknown amino acid and lack of homoserine), the acetylated muramic acid, and a lower G+C content of DNA (63.9–65.2 mol%).

The following characteristics are useful for identification of *Okibacterium fritillariae*: a wide range of carbon sources is used for growth, though polyols are usually not used as a C-source; acids are produced from D-arabinose, D-glucose, mannose, L-rhamnose, sucrose, trehalose and D-xylose; weak hydrolytic activity against many substances, but starch and esculin are decomposed; H_2S is weakly produced; both studied strains tolerate 6% (w/v) NaCl; and strains are generally susceptible to antibiotics (Evtushenko et al., 2002).

The Genus *Plantibacter*

Phenotypically close to the *Rathayibacter* (Zgur-skaya et al., 1992; Sasaki et al., 1998), the genus *Plantibacter* was established by Behrendt et al.

(2002) for actinobacteria isolated from grass phyllosphere and surface litter after mulching the sward.

Other bacteria of this genus, strains VKM Ac-1787 (Kuz1) and VKM Ac-1788 (Kuz2), were isolated from plant galls induced by the plant parasitic nematodes of the subfamily Anguininae and presumably referred to as "*Rathayibacter* sp." as they had DAB in the cell wall and the major menaquinone was MK-10 (typical of *Rathayibacter*; Evtushenko et al., 1994). Subsequently, Altenburger et al. (1997), who studied polyamines in coryneform bacteria, including representatives of strains from plant galls, reported that the polyamine patterns of VKM Ac-1787 and VKM Ac-1789 did not display the characteristic features of the genus *Rathayibacter*. Later, these bacteria were demonstrated to differ phylogenetically from *Rathayibacter* spp. and tentatively assigned to a new genus named "*Anguinibacter*" (Dorofeeva et al., 1999; Shramko et al., 1999).

Phylogeny

Organisms of the genus *Plantibacter* form a tight phylogenetic cluster in the family Microbacteriaceae branch (Fig. 1), showing high 16S rDNA binary sequence similarity to *Okibacterium* (Evtushenko et al., 2002).

Taxonomy

The genus *Plantibacter* is characterized by aerobic, nonsporeforming, nonmotile irregular cells. Oxidase test with tetramethyl-*p*-phenylenediamine varies between the species. *Plantibacteria* have the B group peptidoglycan based upon L-DAB, contain also D-glutamic acid, D-alanine and glycine typical of the type B2 γ murein (Schleifer and Kandler, 1972), and the muramic acid is acetylated. Rhamnose is the predominant cell wall sugar. The major menaquinones are MK-10, MK-10, 9 or MK-10, 11, depending on the species (Tables 1 and 9). The predominant cytochrome oxidase, another component of the respiratory chain, is *aa*₃; some species synthesize quinole oxidases *bo*₃ or *bb*₃. The fatty acid profiles include mainly saturated, *iso*- and *anteiso*-branched acids; minor amounts of straight-chain saturated acids occur. The content of polyamines is low; spermidine and 1,3-diaminopropane predominate. The DNA G+C content is 67–70 mol% (Altenburger et al., 1997; Behrendt et al., 2002; Trutko et al., 2003; Evtushenko et al., submitted).

Currently, the genus *Plantibacter* includes one validly described species, *Plantibacter flavus* (Behrendt, 2002). Three other new species, "*Plantibacter agrosticola*," "*Plantibacter elymi*"

and "*Plantibacter cousiniae*," from plant galls induced by three plant parasitic nematodes of the subfamily Anguininae will be described (Evtushenko et al., submitted). These three putative species differ in some chemotaxonomic characteristics (see subsection Identification in this Chapter), but are almost undistinguishable from each other physiologically. The limited number of physiological properties differentiating the species was previously also noted for some other species belonging to genera, members of which occur in plant phyllosphere or other habitats and are adapted to similar biological, physicochemical and nutritional conditions (Rainey et al., 1995a; Szallas et al., 1997; Pukall et al., 1999; Behrendt et al., 2001; Behrendt et al., 2002; Tsukamoto et al., 2001).

Habitat

Plantibacteria occur in plants and related sources worldwide and may be found in soil. The species *Plantibacter flavus* was isolated from the grass phyllosphere and the surface litter after mulching the sward (Behrendt et al., 2002). *Plantibacter* sp. (*Microbacterium* sp.) strain LB030 was shown to be an endophyte of above-ground plant tissues of agronomic crops (Zinniel et al., 2002). Uncultured *Plantibacter* sp. (clone Q2-28 C8) was discovered in the rhizosphere of potato (Heuer et al., 2002). Many strains of plantibacteria were found in plant galls induced by highly specialized plant parasitic nematodes of the subfamily Anguininae. Strains assigned to "*Plantibacter agrosticola*," "*Plantibacter elymi*" and "*Plantibacter cousiniae*" seem to be strictly associated with *Agrostis* sp. (probably *Agrostis capillaris* L.), *Elymus repens* (L.) Gould., and *Cousinia onopordioides* Ledeb, which are host plants for the nematodes *Anguina agropyri*, *Anguina agrostis* and *Mesoanguina picridis*, respectively. They constituted a significant proportion of microorganisms grown from ground gall suspensions or obtained from relatively old galls, whereas they were not recovered from samples outside the galls, from other plants without nematode infection, or from galls induced by other nematodes (Evtushenko et al., submitted). This finding may be judged as an indirect evidence that certain *Plantibacter* spp. use plant parasitic anguinid species as vectors, as also reported for *Rathayibacter* spp. (Bird, 1981; Bird, 1985; Riley, 1987). On the other hand, plantibacteria in galls may descend from the phyllosphere (Behrendt et al., 2002) or from healthy plant tissue (Zinniel et al., 2002). Anguinids may facilitate colonization of sites of gall formation with plantibacteria providing an entry route for the endophytes, as also reported for other endo-

phytic bacteria and plant parasite nematodes (Hallmann et al., 1997).

Except for the gumming disease caused by “*Corynebacterium agropyri*” (O’Gara, 1916; Cummins et al., 1974) that might correspond to *Plantibacter* spp., there are no examples of plant pathogenic properties in plantibacteria. Strains of “*Corynebacterium agropyri*” are phenotypically similar to *Rathayibacter* (Cummins et al., 1974; Murray, 1986) and *Plantibacter* strains. “*Corynebacterium agropyri*” CS 35 (T. D. Murray, CA-1), investigated in greater detail, had DAB in the cell wall and clearly differed from *Rathayibacter* in its allozyme pattern (Riley et al., 1988). The strain showed specific adhesion to *Anguina* species, but pathogenicity was not observed (Riley et al., 1988). Like “*Plantibacter elymi*,” strains of “*Corynebacterium agropyri*” were associated with wheat grasses and isolated from *Pascopyrum smithii* (Rydb.) A. Love (syn. *Agropyron smithii* Rydb.) or from 30- to 40-year-old herbarium specimens of the same plant and *Elymus trachycaulus* (Link) Gould ex Shinners [syn. *Agropyron trachycaulum* (Link) Malte] and *Elymus lanceolatus* (Scribn. and J. G. Sm.) Gould (syn. *Agropyron riparium* Scribn. and J. G. Sm.) (O’Gara, 1916; Cummins et al., 1974; Murray, 1986).

Isolation

Plantibacter spp. can be isolated from plants and plant-related sources as indicated in the subsection Habitat in this Chapter. The approaches described by Behrendt et al. (1997), Hallmann et al. (1997), and Zinniel et al. (2002) may be applied for isolation (see the section The Genus *Clavibacter* in this Chapter and the subsection Isolation in this Chapter). CNS medium (Vidaver and Davis, 1988) or a modified CNS medium without lithium chloride was successfully used for isolation of endophytic bacteria, including plantibacteria (Zinniel et al., 2002). The procedure of preparing a sample for isolation of bacteria from plant galls is described in the section The Genus *Agreia* in this Chapter. The ground gall suspension is plated onto an appropriate medium, e.g., NWG agar, tenfold diluted CB medium (Evtushenko et al., 1994; Evtushenko et al., 2001), or 2AR agar (Behrendt et al., 1997). Sterilization of gall surface reduces the amount of Gram-negative bacteria, which also develop on isolation media.

Identification

Plantibacteria clearly differ from their phylogenetic neighbor, *Okibacterium*, in DAB-based peptidoglycan and the major menaquinone MK-10, or MK-10 combined with MK-9 (Tables

1 and 9). Phenotypically, plantibacteria resemble members of the genus *Rathayibacter* and might be confused with organisms of this genus, which are also mesophilic, have the same cell size and shape, peptidoglycan of the B2 γ type, the major menaquinone MK-10 (Table 1), and association with grasses and nematodes of the subfamily Anguininae (Riley and Ophel, 1992; Zgurskaya et al., 1993b; Dorofeeva et al., 2002). FT-IR spectroscopy, as a physicochemical whole-cell fingerprint technique (Oberreuter et al., 2002), is extremely helpful to cluster members of these genera at the phenotypic level (Behrendt et al., 2002). *Plantibacter* strains differ from *Rathayibacter* spp. in the composition of menaquinones. Plantibacteria produce cytochrome oxidase *aa*₃, while *Rathayibacter* spp. synthesize mainly cytochrome oxidase *bb*₃ or both *bb*₃ and *aa*₃, depending on growth conditions (Trutko et al., 2003). *Plantibacter* spp. may differ from *Rathayibacter* in the pattern and total amount of polyamines (Altenburger et al., 1997). Besides, *Rathayibacter* and *Plantibacter* species that are both associated with anguinids usually inhabit plant galls induced by different nematodes and, respectively, occur in different plants (Table 13).

The oxidase test, growth at 6% NaCl, composition of menaquinones, the G+C content of DNA, and some other characteristics can be used to identify plantibacteria at the species level. All 12 strains of three species from plant galls are also clearly separated from each other by cell wall sugars, terminal oxidases of respiratory chains, and the FT-IR spectra (L. I. Evtushenko et al., submitted). The species affiliation of strains is consistent with their isolation source, i.e., plant galls on *Agrostis* sp., *Elymus repens* and *Cousinia onopordioides*, induced by highly specialized plant parasitic nematodes, *Anguina agrostis*, *Anguina agropyri* and *Mesoanguina picridis*, respectively (Table 14).

Applications

Colonization of crops with endophytic plantibacteria (Zinniel et al., 2002) suggests that they may be used in future applications, such as for controlling certain plant diseases or promoting plant growth. This approach allows one to obtain plants with improved capabilities without genetic modification of plants (Hallmann et al., 1997). Taking into account the possible role of plantibacters in anguinid-bacterial complexes, it may be supposed that some species possess certain enzymes degrading plant cells and, probably, some antibiotic substances related to their involvement in the nematode-bacterial complexes.

Table 13. Characteristics that differentiate the genera *Plantibacter* and *Rathayibacter*.^a

Characteristic	Plantibacter	Rathayibacter
Colony color	Yellow	Yellow, pink-orange
Major menaquinone	MK-10 / MK-9, 10 / MK-10,11	MK-10

The Genus *Rathayibacter*

The genus *Rathayibacter* (Zgurskaya et al., 1993b), previously referred to the genus *Clavibacter* (Davis et al., 1984b), was proposed to accommodate some plant pathogenic species containing DAB as diamino acid in the cell wall

peptidoglycan and unsaturated menaquinone MK-10.

The first documented species of the genus were *Rathayibacter rathayi* (originally, "*Aplanobacter rathayi*") and *Rathayibacter tritici* (formerly "*Pseudomonas tritici*") described by Smith (1913) and Hutchinson (1917), respectively. The

bacteria were reclassified several times and then allocated to the genus *Corynebacterium* as separate species (Cummins et al., 1974). The third species of the genus, "*Corynebacterium iranicum*," was described by Scharif (1961). However, only *Corynebacterium rathayi* was included in the Approved List (Skerman et al., 1980). Subsequently, Carlson and Vidaver (1982) supported the separate species status of *Corynebacterium iranicum* and *Corynebacterium tritici* on the basis of cellular protein analysis, which also corresponded to the phenotypic study results reported by Dye and Kemp (1977), bacteriocin production (Gross and Vidaver, 1979b), and also menaquinone patterns (Collins and Jones, 1980a). Although the organisms differed from *Corynebacterium sensu stricto* in the cell wall peptidoglycan and lipid composition (Schleifer and Kandler, 1972; Fiedler et al., 1973b; Collins and Jones, 1980a), the generic name *Corynebacterium* was retained for the purpose of convenience and practicality and the species were validated under this generic name (Carlson and Vidaver, 1982).

Davis et al. (1984b) established the genus *Clavibacter* for plant pathogenic bacteria with DAB in the cell and, together with *Corynebacterium michiganensis* and the plant pathogens causing ratoon stunt disease (currently *Leifsonia*), reclassified *Corynebacterium rathayi*, *Corynebacterium tritici* and *Corynebacterium iranicum* into *Clavibacter*. Zgurskaya et al. (1993b) proposed that these three species and *Clavibacter* sp., known as the annual ryegrass toxicity (ARGT) bacteria (Stynes and Bird, 1980; Stynes and Bird, 1983; Riley, 1987), be reclassified into the newly established genus *Rathayibacter*. The proposal was based on differences between these organisms and *Clavibacter sensu stricto* in predominant menaquinones, morphological and physiological characteristics, DNA-DNA relatedness, and data provided earlier, e.g., on chemotaxonomy (Minnikin et al., 1978; Collins and Jones, 1980a; Collins, 1983a), physiology (Dye and Kemp, 1977), serology (Riley, 1987), and allozyme (Riley et al., 1988) and whole cell protein patterns (Carlson and Vidaver, 1982). The separation was also consistent with the affiliation of individual bacterial groups to host plants (Dye and Kemp, 1977) and associated diseases as well as to nematode vectors (Riley, 1987; Riley and McKay, 1990; Riley and Ophel, 1992). Subsequently, separation of *Rathayibacter* spp. from *Clavibacter* was supported by the analyses of 16S rRNA gene sequences (Rainey et al., 1994; Takeuchi and Yokota, 1994). In 1998, Sasaki et al. reclassified the ARGT bacteria, which had been validly described by Riley and Ophel (1992) as *Clavibacter toxicus*, into *Rathayibacter*. Recently, two

new species, *Rathayibacter festucae* and *Rathayibacter caricis*, have been added to the genus (Dorofeeva et al., 2002).

Phylogeny

Members of the genus *Rathayibacter* form a tight cluster within the Microbacteriaceae phylogenetic branch, which is linked to the genus *Curtobacterium* cluster (Fig. 1). The species *Rathayibacter toxicus* branches mostly distant from all other species comprising the genus.

Taxonomy

The genus *Rathayibacter* currently includes six species: *Rathayibacter rathayi* (Smith, 1913), *Rathayibacter tritici* (Carlson and Vidaver, 1982), *Rathayibacter iranicus* (Carlson and Vidaver, 1982) Zgurskaya et al. 1993b, *Rathayibacter toxicus* (Riley and Ophel, 1992) Sasaki et al. 1998, *Rathayibacter caricis*, and *Rathayibacter festucae* (Dorofeeva et al., 2002).

Members of the genus are characterized by nonsporeforming, nonmotile, irregular rods (2.0–2.5 $\mu\text{m} \times 0.5\text{--}0.8 \mu\text{m}$), which occur singly or in pairs with diphtheroid arrangements. Primary branching is not observed. In a 5–7 d culture, rods are replaced by cocco-bacilliaric forms, single or arranged in pairs, short chains or clumps. Some fresh isolates exhibited a visible rod-coccoid cycle. Strains are aerobic, catalase positive, and usually show a negative or weakly positive oxidase reaction with the tetramethyl-*p*-phenylenediamine test. Thermal optimum is 24–26°C, no growth occurs at 7 or 37°C. Peptidoglycan is of the B2 γ type (Schleifer and Kandler, 1972) on the basis of L-2,4-diaminobutyric acid (L-DAB; Sasaki et al., 1998) and contains the amino acids glycine, glutamate, DAB, and alanine in a molar ratio close to 1:1:2:1. Cell wall sugars are glucose, rhamnose, and mannose. Xylose, galactose and fucose may also occur in some species. No mycolic acids are present. The major menaquinone is MK-10, and MK-8, MK-9 and MK-11 may be detected as minor components. Principal phospholipids are phosphatidylglycerol and diphosphatidylglycerol, and traces of another unidentified phospholipid with a low R_f value may be revealed. Saturated anteiso- and iso-methyl branched fatty acids are predominant (Zgurskaya et al., 1993b; Sasaki et al., 1998; Dorofeeva et al., 2002).

Consistent with their affiliation to host plants and nematode vectors (Table 15), the differentiation between the species is based on cultural, morphological, physiological and chemotaxonomic characteristics.

^aData from Sabet (1954), Gupta and Swarup (1972), Price et al. (1979), Vidaver (1982), Riley and McKay (1990), and Riley and Ophel (1992).

^bThe *Rathayibacter toxicus*-like strains were isolated from *Agrostis avenacea* and *Polypogon monspeliensis* infested with an *Anguina* sp. which differs from *Anguina funesta* (McKay et al., 2001).

^cNo nematode infestation of *Carex* sp. was observed, but the sedge species are known to be host plants for *Heteroanguina caricis* (Krall, 1991).

^d*Anguina* sp. parasitizing *Dactylis glomerata* is phylogenetically distant from *Anguina agrostis* sensu stricto and belongs to a new undescribed species (Powers et al., 2001; S. A. Subbotin, personal communication).

Data from Dye and Kemp (1977), Riley and Ophel (1992), Zgurskaya et al. (1992), Sasaki et al. (1998), and Dorofeeva et al. (2002).

Habitat and Phytopathogenicity

The main habitats of *Rathayibacter* spp., most of which are plant pathogens and associated with plant parasitic nematodes of the subfamily Anguininae, are considered to be their host plants and related sources (Table 15). A representative of *Rathayibacter festucae* was found in a leaf gall of fescue (*Festuca rubra* L., the family Poaceae), and *Rathayibacter caricis* was associated with *Carex* sp. belonging to the family Cyperaceae; there are no data on plant pathogenic properties of these two species (Dorofeeva et al., 2002). Several strains identified as *Rathayibacter* sp. were isolated together with *Clavibacter michiganensis* subsp. *michiganensis* (Labadie and Hebraud, 1997). “*Rathayibacter biopuresis*” was obtained from the gut of the

marine worm *Notomastus lobatus* (Wong et al., 1996; Wong et al., 1999). There are no phylogenetic data supporting the taxonomic position of these strains.

GUMMING DISEASE CAUSED BY *RATHAYIBACTER* SPECIES The plant pathogens *Rathayibacter tritici*, *Rathayibacter rathayi*, *Rathayibacter iranicus* and *Rathayibacter toxicus* cause a gumming disease, which particularly affects inflorescences and usually is characterized by yellow bacterial slime on developing seedheads, stems and leaves of a plant host (Sabet, 1954; Scharif, 1961; Gupta and Swarup, 1972; Vidaver, 1982; Bradbury, 1986; Riley and Ophel, 1992). *Rathayibacter tritici* and *Rathayibacter iranicus* occur in wheat (*Triticum aestivum* L.), and *Rathayibacter rathayi*

is associated with orchard grass (*Dactylis glomerata* L.; Cummins et al., 1974; Carlson and Vidaver, 1982; Collins and Bradbury, 1992). Some weed grasses were reported to be natural hosts of bacteria referred to as "*Rathayibacter tritici*" (Collins and Bradbury, 1986). However, there are no phylogenetic data supporting the taxonomic position of these bacteria. Experimentally, some Poaceae plants have been successfully inoculated by *Rathayibacter tritici* and *Rathayibacter rathayi* using the nematode *Anguina tritici* as vector (Collins and Bradbury, 1986). *Rathayibacter toxicus* inhabits ryegrass (*Lolium rigidum* Gaud.) and probably some related grasses and is responsible for annual rye grass toxicity (Bird and Stynes, 1977; Riley and Ophel, 1992; Johnston et al., 1996). Pathogenicity of cultured *Rathayibacter toxicus* on ryegrass has never been shown, although its association with field-collected bacterial galls has been demonstrated (Price et al., 1979; Riley and Ophel, 1991b).

RATHAYIBACTER-ANGUINA DISEASE COMPLEXES

Under natural conditions, the gumming disease is transmitted by vector nematodes of the subfamily Anguininae, which are highly specialized parasites of plants where they induce specific galls in various organs (Gupta and Swarup, 1972; Price, 1979; Bird, 1981; Riley, 1987; Krall, 1991; McKay and Ophel, 1993; Evtushenko et al., 1994). Strains of each *Rathayibacter* species were observed or suggested (Sabet, 1954; Gupta and Swarup, 1972; Bradbury, 1986; Riley, 1987; Riley and McKay, 1990; Dorofeeva et al., 2002) to be associated with their specific nematode vector, namely *Anguina tritici*, *Anguina funesta*, *Anguina graminis* or *Anguina agrostis* (Southey et al., 1990; Krall, 1991; Table 15). It should be noted that *Anguina agrostis* (Steinbuch, 1799), reported to infest several plants, is a heterogeneous species (Southey et al., 1990). "*Anguina agrostis*" parasitizing *Dactylis glomerata* (the host plant of *Rathayibacter rathayi*) belongs to a new undescribed nematode species (Powers et al., 2001; S. A. Subbotin, personal communication). The bacteria transmitted by the nematode *Anguina funesta* (synonymized previously by some authors with *Anguina agrostis*) and cited in some earlier publications as *Corynebacterium rathayi*, *Clavibacter rathayi*, *Corynebacterium* sp., or *Clavibacter* sp. (e.g., Cummins et al., 1974; Bird et al., 1980; Stynes and Bird, 1980; Stynes and Bird, 1983; Bird, 1981; Bird, 1985; Vidaver, 1982; Murray, 1986) are actually strains of *Rathayibacter toxicus* or closely related organisms.

Bacteria assigned to *Rathayibacter toxicus* are not genetically homogeneous (Riley et al., 1988; Riley and Ophel, 1992). Strains from *Agrostis*

avenacea J. F. Gmel. and *Polypogon monspeliensis* (L.) Desf. were indistinguishable from *Rathayibacter toxicus* in colony morphology, serological reactions, and bacteriophage specificity, but were considerably different in allozyme pattern. In addition, they were associated with an *Anguina* sp. which differs from *Anguina funesta*, a vector for *Rathayibacter toxicus* (McKay et al., 1993; Powers et al., 2001).

Rathayibacter rathayi was reported to be transferred experimentally by *Anguina tritici* into *Triticum* sp., a host of *Rathayibacter tritici*, and like *Rathayibacter tritici*, to cause a disease in this plant (Sabet, 1954). *Triticum dicoccum*, *T. durum* and *T. pyramidale* were successfully inoculated by *Rathayibacter tritici* using the nematode *Anguina tritici* (Collins and Bradbury, 1986). *Rathayibacter rathayi* and *Rathayibacter tritici* are transmitted experimentally by *Anguina funesta* (the nematode vector for *Rathayibacter toxicus*) and colonize ryegrass without doing harm to the plant (Riley and Yan, 1999).

No visible symptoms of nematode infestation were observed for *Carex* sp. from which *Rathayibacter caricis* has been isolated (Dorofeeva et al., 2002). However, knowledge of habitats and biology of other *rathayibacteria* and *anguinids* suggests that *Rathayibacter caricis* is also associated with a nematode of the subfamily Anguininae. The sedge species are known to be host plants for *Heteroanguina caricis*, belonging to the same subfamily Anguininae (Krall, 1991), and this nematode may be the vector for *Rathayibacter caricis*.

Relationship Between Components in the Rathayibacter-Anguina Disease Complexes

Little is known about the relationship between components in the *Rathayibacter-Anguina* plant pathogenic complexes, including also bacteriophages (Bird et al., 1980; Riley and Gooden, 1991a; Ophel et al., 1993). The available data suggest that this association is of mutual benefit for *Rathayibacter* and nematode and may be regarded as symbiosis. Nematodes carry bacteria on their surface into the growing points of host plants (Price et al., 1979; Bird, 1981; Bird, 1985; Riley and McKay, 1990) and create wounds in plants, providing avenues for the bacteria to enter tissue and ensuring the leakage of plant nutrients, supporting external bacterial colonization (Hallmann et al., 1997). The bacteria inhabit also many galls induced by nematodes in seeds, leaves, stems, or roots (Price, 1979; Bird, 1981; Krall, 1991; Ophel et al., 1993; Evtushenko et al., 1994). The bacteria within desiccated mature galls are resistant to environmental perturbations (isolated from galls after having been dry for several years; Bird, 1981). In turn, nematodes

seem to depend in their life cycles on the associated bacteria. The bacteria are supposed to facilitate the development of nematode larvae within the galls and the release of nematodes, destroying gall envelope by fermentative activities at suitable environmental conditions (Bird, 1981; Bird, 1985). As in case of other nematode-associated bacteria (Akhurst, 1982), they may protect nematode larvae from certain bacterial and fungal infections by producing antimicrobial substances, e.g., bacteriocins (Gross and Vidaver, 1979b) or enzymes (De Bruyne et al., 1992). It is unknown whether the toxins produced by *Rathayibacter toxicus* and related bacteria have any effect on the nematode (Agrios, 1997).

Corynetoxin Produced by Rathayibacter Toxicus and Some Related Bacteria Corynetoxin is produced by *Rathayibacter toxicus* when the bacterium is infected with a bacteriophage and produces bacteriophage structural proteins (Ophel et al., 1993). The mechanism by which the bacteriophage affects toxin production is unknown. A small bacteriophage genome could not encode both the gene for toxin biosynthesis and the genes for bacteriophage replication and survival. The bacteriophage may encode a regulatory gene that switches on toxin production or a gene encoding a final step in the corynetoxin biosynthetic pathway. Alternatively, it is possible that bacteriophage infection makes cells more permeable to export of toxin (Ophel et al., 1993). Bacteriophages with similar DNA restriction patterns were also isolated from the toxic *Rathayibacter toxicus*-like strains associated with *Anguina* sp., parasitizing *Agrostis avenacea* and *Polypogon monspeliensis* (McKay et al., 1993).

The corynetoxin is chemically and biologically similar to tunicamycin (Vogel et al., 1982; Cheeke, 1995), which inhibits N-linked protein glycosylation (Jago et al., 1983; Crosti et al., 2001). Tunicamycin is active against fungi, yeasts, Gram-positive bacteria, especially *Bacillus* sp., and viruses (Korzybski et al., 1978). Corynetoxin causes defective formation of blood components of the reticulo-endothelial system and is harmful to grazing animals (Finnie and Mukherjee, 1986; Cheeke, 1995; Finnie, 2001). The corynetoxin may play a role in plant pathogenicity. Tunicamycin, together with brefeldin A, has recently been proved able to induce a strong acceleration of the plant cell death, changes in cell and nucleus morphology, and an increase in DNA fragmentation. These compounds, interfering with the activities of endoplasmic reticulum and of Golgi apparatus, strongly induce a form of programmed plant cell death showing apoptotic features (Crosti et al., 2001).

Other Rathayibacter-Like Bacteria Associated with Anguinid Nematodes The *Rathayibacter*-like bacteria isolated from plant galls induced by *Mesoanguina pictidis* on *Cousinia onopordialis* Ledeb. (family Asteraceae) and *Anguina agropyri* on *Elymus repens* (L.) Gould (Evtushenko et al., 1994) were later shown to be members of the genus *Plantibacter* (Shramko et al., 1999; Evtushenko et al., submitted). Isolates of "*Corynebacterium agropyri*" (O'Gara, 1916; Cummins et al., 1974; Murray, 1986), isolated from wheat grasses and shown to have specific adhesion to *Anguina* species (Riley and McKay, 1990), are likewise not members of *Rathayibacter* as they differ significantly in the allozyme pattern (Riley et al., 1988), but they might correspond to *Plantibacter* (see the section The Genus *Plantibacter* in this Chapter). The discovery of unidentified bacteria in *Festuca rubra* subsp. *commutata* infested with the nematode *Anguina* sp., showing toxicity for livestock, was reported by Galloway (1961) and Bird (1981). There are no data showing whether the above bacteria belong to *Rathayibacter toxicus*, *Rathayibacter festucae*, or represent new species of *Rathayibacter* or other genera. Similar bacteria may be responsible for the toxicity of *Festuca rubra*, infested with *Anguina* sp. ("*Anguina agrostis*"), for grazing animals, as observed between 1943 and 1949 (Bird, 1981).

Isolation

To isolate *Rathayibacter* spp. from diseased plants, certain common rules on the isolation of many plant pathogenic bacteria should be followed to reduce contamination with other bacteria that also inhabit plants. For successful isolation, bacteria-containing parts of plants (visible bacterial slime) are used. Developing seed-heads and leaves are selected in case the plants are determined to be in the earlier phase of bacterial (nematode) infection. The selected piece of tissue should be carefully excised with sterile instruments, placed in sterile water, and left for a period of few minutes to hours to release the bacteria. Plant galls inhabited by bacteria are also a suitable source of isolation. The procedure of preparing a sample for isolation of bacteria from plant galls is described in the section The Genus *Agreia*. The obtained suspensions of bacteria or plant (gall) material are plated onto a suitable medium. *Rathayibacter* spp. can be isolated on the media recommended for isolation of *Clavibacter*. CNS agar medium (see the section The Genus *Clavibacter* in this Chapter) was reported to be helpful for isolating *Rathayibacter tritici* (Gross and Vidaver, 1979a). A number of media based on glucose, peptone, yeast extract, and casamino acids are suitable for

growing rathayibacteria. *Rathayibacter toxicus* grows well on 523M agar medium (Riley and Ophel, 1993), CB (Zgurskaya et al., 1993b), and R medium (Yamada and Komagata, 1972a; Sasaki et al., 1998).

Identification

GENERIC LEVEL *Rathayibacter* spp. form a coherent phylogenetic cluster and novel isolates can be easily attributed to the genus on the basis of partial 16S rRNA gene sequences or 16S rDNA restriction analysis (Lee et al., 1997b; Shramko et al., 1999). *Rathayibacter* can also be differentiated from most genera of the family Microbacteriaceae at the phenotypic level by the presence of DAB in the cell wall and the major menaquinone MK-10 (Table 1). Phenotypically, the *Rathayibacter* species resemble organisms of the genus *Plantibacter*. They can be readily differentiated from plantibacteria by FT-IR spectra (Behrendt et al., 2002). Menaquinone composition (Behrendt et al., 2002; Evtushenko et al., submitted), amount and pattern of polyamines (Altenburger et al., 1997), and terminal cytochrome oxidases *bb*₃ or *bb*₃ combined with *aa*₃ (Trutko et al., 2003) are additional useful diagnostic traits (Table 13).

SPECIES LEVEL At the species level, *Rathayibacter* strains are relatively easy to identify when isolated from a known plant host with clear disease symptoms and when the nematode vector is known. Species affiliation of strains is achieved by color of colonies, growth rate, cell wall sugar composition, and some physiological properties (Table 15), as well as allozyme profiles (Riley et al., 1988) and 16S rDNA RFLP patterns (Lee et al., 1997b; Shramko et al., 1999).

The immunodiffusion technique is useful to differentiate *Rathayibacter toxicus* from *Rathayibacter tritici*, *Rathayibacter rathayi* and *Rathayibacter iranicus* as well as *Rathayibacter iranicus* from *Rathayibacter tritici* and *Rathayibacter rathayi*, although serum against *Rathayibacter iranicus* gave a reaction with some *Rathayibacter tritici* strains (Riley, 1987). Polyclonal ELISA tests have been applied to detection of *Rathayibacter toxicus* in paddocks and hay without any problems of crossreactivity with other species (Riley, 1987; McKay and Ophel, 1993). However, other toxic strains from *Agrostis avenacea* and *Polypogon monspeliensis*, which might not be members of *Rathayibacter toxicus* (as derived from different allozyme patterns), were reported to be indistinguishable from *Rathayibacter toxicus* in serological reactions (McKay et al., 1993). Plant pathogenicity testing may be difficult, since nematodes are necessary vectors for transmission of infection by *Rathayibacter* pathogens

(Vidaver and Davis et al., 1988), and crossreactions are possible (Sabet, 1954). Cases where rathayibacteria are isolated from an unusual host plant, plant galls induced by anguinids not included in Table 15, or any other unusual source may represent a new species and should be subjected to thorough taxonomic analysis.

Applications

Much of the present annual ryegrass toxicity management has focused on the control of ryegrass (Riley and Yan, 1999). Control by herbicides is often ineffective as it is associated with a rapid increase in herbicide resistance. The recent finding that some strains of *Rathayibacter rathayi* and *Rathayibacter tritici* may be transmitted experimentally by *Anguina funesta* (the nematode vector for *Rathayibacter toxicus*) and may colonize ryegrass, displacing *Rathayibacter toxicus*, offers a potential for novel biocontrol (Riley and Yan, 1999). The physiological and enzymatic activities of rathayibacteria (De Bruyne et al., 1992) as well as the ability to produce some antibiotic substances (Gross and Vidaver, 1979b) demonstrate that they may be useful for screening of metabolites and enzymes, which are applicable for biotechnology and pharmaceuticals. A strain identified as *Rathayibacter* sp. produced cephalixin-chloroperoxidase and other enzymes and use of this strain in a new biomethod for producing cefaclor, an antibiotic of the cephalosporin class, was claimed (Chen and Wong, 1997; Wong et al., 1999). Collagenolytic strains identified as *Rathayibacter* sp. produce an enzyme that is able to degrade native collagen, gelatin and probably other proteins from plants, sharing sequence homologies with collagen; it may be of major importance for degradation of the collagen of different plant parasitic nematodes (Labadie and Hebraud, 1997).

The Genus *Subtercola*

The genus *Subtercola*, including *Subtercola boreus* (the type species) and *Subtercola frigoramans*, was established by Männistö et al. (2000) for aerobic psychrophilic coryneform bacteria isolated from cold groundwater. Another species, *Subtercola pratensis* proposed by Behrendt et al. (2002), has recently been reclassified to the genus *Agreia* (Schumann et al., 2003) and is considered in the respective section.

Phylogeny

Organisms of the genus form a distinct phylogenetic branch within the family Microbacteriaceae cluster. The phylogenetic neighbor of the genus

Subtercola as inferred from 16S rRNA gene sequence analysis is the genus *Agreia* (Fig. 1).

Taxonomy

Members of the genus form pale to bright yellow, circular, convex, and smooth colonies. Cells are nonmotile, irregular, thin (0.2–0.3 µm) rods, single or as v-forms. Endospores are not produced. The bacteria grow at temperature 2–28°C, with the optimum at 15–17°C. The characteristic diamino acid of cell wall peptidoglycan is L-DAB and the peptidoglycan type is B2γ. The predominant menaquinones are MK-9 and MK-10. The whole cell sugars are rhamnose, ribose, xylose and mannose or may be glucose, rhamnose and xylose, depending on the strains. The polar lipids are phosphatidylglycerol, diphosphatidylglycerol, one unknown phospholipid, and two glycolipids. The main cellular fatty acids are 12-methyl-tetradecanoic acid (*anteiso*-15:0), 14-methylpentadecanoic acid (*iso*-16:0) and 14-methyl-hexadecanoic acid (*anteiso*-17:0). The whole-cell methanolysates of *Subtercola* sp. contain also 1,1-dimethoxy-*anteiso*-pentadecane (*anteiso*-15:0 DMA) and 1,1-dimethoxy-*iso*-hexadecane (*iso*-16:0 DMA) in amounts comparable to those of fatty acids. The G+C content of DNA is 64–68 mol% (Männistö et al., 2000).

The genus contains two species, *Subtercola boreus* and *Subtercola frigoramans*, which differ in the 16S rRNA gene sequence and in phenotypic characteristics (Männistö et al., 2000; see subsection Identification in this Chapter).

Habitat

Subtercola boreus and *Subtercola frigoramans* were isolated from the groundwater with a low stable temperature of about 7°C, pumped from a shallow aquifer (18 m deep) located under a glacial gravel ridge in Southern Finland. The water was highly humic (with dissolved organic carbon, 4–13 mg/liter) and rich in iron (15 mg/liter; Männistö et al., 2000).

The study of lipid composition in *Subtercola* has revealed an interesting effect of temperature on cellular fatty acid compositions, which may be related to its psychrophilic mode of life. Decreases in temperature influenced both fatty acid and dimethyl acetal (DMA) compositions of the strains. When growth temperature was lowered from 25 to 4°C, the proportion of *anteiso*-15:0 DMA, the main DMA in the whole-cell methanolysates, increased from 10–11 to 14–20%. Accordingly, the *anteiso*-17:0 and *anteiso*-15:0 contents were reduced and the amounts of *anteiso*-17:0 DMA and *iso*-16:0 DMA fell (Männistö et al., 2000). The authors argued that the low growth temperature favored the synthe-

sis of DMAs with shorter carbon chain lengths, a shift from *iso*-branched DMAs to *anteiso*-branched congeners, or both. The biological function of plasmalogens is not known, but Kaufman et al. (1990) showed that membranes of *M. elsdenii* (with a high plasmalogen content) were more ordered than membranes devoid of plasmalogens. This may indicate that changes in the plasmalogen derived 1,1-dimethyl acetal composition may influence the membrane fluidity (Männistö et al., 2000).

Isolation

The strains were isolated on PYGV agar used earlier for isolation of *Ancalomicrobium* and *Prosthecomicrobium* (Staley, 1968) at 7°C. The cultures grow also on trypticase soy (TS) agar or R2A agar (BBL Microbiology Systems, Cockeysville, MD, United States). The optimum growth is at 15–17°C.

Identification

Novel isolates can be preliminarily identified as members of the genus *Subtercola* by their unique combination of chemotaxonomic characteristics (Tables 1 and 9). The most striking properties, which differentiate *Subtercola* from other genera of the family Microbacteriaceae, are the growth temperature optimum, the presence of DAB and hydroxyglutamic acid in the cell wall peptidoglycan, along with fatty acid composition and large amounts of *anteiso*-1,1-dimethoxy-pentadecane (*anteiso*-15:0 DMA) and *iso*-1,1-dimethoxyhexadecane (*iso*-16:0 DMA) in whole-cell methanolysates (Männistö et al., 2000). Bacteria of the genus *Subtercola* differ from their closest phylogenetic neighbor, the genus *Agreia*, by the major menaquinones MK-9 and MK-10, lack of ornithine in the cell wall, and some other properties.

The type strains of the two species of *Subtercola* are significantly different in their 16S rRNA gene sequence (97% similarity), and most nucleotide changes (in about 30 positions) are located at the 5' 400–500 nucleotides (*E. coli* numbering). This difference can be used to preliminarily identify the strains of the species *Subtercola boreus* and *Subtercola frigoramans* at the phylogenetic level, using partial sequences. Strains of the two species can be separated by their cell morphology, cell wall sugar composition, the G+C content of DNA, and physiological features (Table 16). *Subtercola boreus* is characterized by irregular, short, slightly curved rods, 0.2–0.3 × 0.6–1.0 µm, while the rod-shaped cells of *Subtercola frigoramans* are larger and more pleomorphic, 0.3–0.4 × 0.9–1.5 µm. Young cells of *Subtercola frigoramans* can also be swollen at the

Table 16. Characteristics that differentiate two species of the genus *Subtercola*.

Abbreviation: pNP, *p*-nitrophenyl.

*The species *Subtercola pratensis* is considered in the section The Genus *Agreia*.

Data from Männistö et al. (2000).

pole or in the middle. The type strain of the species *Subtercola boreus* has rhamnose, ribose and small amounts of xylose and mannose in the cell wall, whereas the type strain of *Subtercola frigoramans* is characterized by glucose, rhamnose and small amounts of xylose. The latter species exceeds *Subtercola boreus* in the spectrum of assimilated carbon sources (Männistö et al., 2000).

Other Microorganisms of the Family Microbacteriaceae

Besides the microorganisms belonging to the 15 validly described genera reviewed in the previous sections, a large diversity of other bacteria of the family Microbacteriaceae with uncertain taxonomic positions has been revealed and described invalidly. In this section, representatives of some bacterial groups of the family are considered, which form separate lines of descent and may be nuclei of new genera. Some of such bacteria have been known for a long time and are well characterized, while others have been discovered only recently and/or only data on their 16S rRNA gene sequences are available from public databases. The list of bacteria with uncertain generic position considered in the section is far from being complete. The data presented aim only to demonstrate additional diversity, features and habitats of microorganisms related to the family Microbacteriaceae which have not been described or were mentioned only in passing in the previous sections.

“*Brevibacterium helvolum*” Group

“*Brevibacterium helvolum*” DSM 20419 (X77440) was isolated from butter and has been studied by many authors. The strain has peptidoglycan B2γ, [L-DAB]-D-Glu-D-DAB (Schleifer and Kandler, 1972; Fiedler et al., 1973b), where the proportions of L- and D-DAB are almost equal (Sasaki et al., 1998). The major menaquinone of this strain is MK-9 (Sasaki et al., 1998) and the G+C content is 72.2 mol% (Döpfer et al., 1982). The strain is chemotaxonomically close to the genus *Clavibacter* but distant from it and other genera at the phylogenetic level and supposed to be the nucleus of a new genus (Rainey et al., 1994). Four other strains of “*Brevibacterium helvolum*,” which contain the B2γ peptidoglycan based upon DAB (Schleifer and Kandler, 1972), were isolated from oil-brine in Yabase oil-field, Japan (Komagata and Iizuka, 1964), and assigned to the genus *Curtobacterium* along with some true curtobacteria (Yamada and Komagata, 1972b). These four strains slightly differ from “*Brevibacterium helvolum*” DSM 20419 in the G+C content (65.6–65.9 mol%; Yamada and Komagata, 1972b) and fatty acid composition, which is rather similar to that of *Curtobacterium* spp. (Suzuki and Komagata, 1983). Although some applicable features for strains labelled “*Brevibacterium helvolum*” were reported, only “*Brevibacterium helvolum*” AJ 1458 described by Komagata and Iizuka (1964) seems to be related to the group under discussion. The strain was claimed for the method of microbial production of L-serine (Kubota and Shiro, 1979). Many other publications dealing

with the application or possible use of “*Brevibacterium helvolum*” concern the strains which are outside the above group and belong to the genus *Arthrobacter* (e.g., DeLey and Defloor, 1959; Yorifuji et al., 1995; Kim et al., 2000). The bacterium “*Bacterium helvolum*” was reported to be responsible for septicemia, pericarditis and pleurisy (Brisou et al., 1970). However, there are no chemotaxonomic or phylogenetic data supporting its taxonomic position.

“*Corynebacterium bovis*” Group

“*Corynebacterium bovis*” ATCC 13722 (AF300651) from cow manure, “*Brevibacterium equis*” (AJ251780) from horse infections and several organisms from environment samples (e.g., AB012595) also compose a separate phylogenetic cluster. The cluster is linked to the “*Brevibacterium helvolum*” DSM 20419 line of descent with a 99% bootstrap confidence level. Like “*Brevibacterium helvolum*,” the strain “*Corynebacterium bovis*” ATCC 13722 possesses peptidoglycan based upon DAB, but the structure of the polymer was determined to be [L-Hsr]-D-Gly-D-DAB (Fiedler and Kandler, 1973a; Schleifer and Seidl, 1985). The G+C content of DNA is 73.7 mol% (Döpfer et al., 1982). Further taxonomic studies are required to elucidate whether “*Brevibacterium helvolum*” and “*Corynebacterium bovis*” with related organisms represent a single genus or two different genera.

Microbacteriaceae Diversity Associated with Plants

Numerous examples demonstrate that plants and related sources are typical natural habitats of many bacteria comprising the family Microbacteriaceae. Those include the organisms of the genera *Agreia*, *Clavibacter*, *Curtobacterium*, *Frigoribacterium*, *Leifsonia*, *Microbacterium*, *Okibacterium*, *Plantibacter* and *Rathayibacter*, which were reviewed in the respective sections. Besides the known and many new species of these genera (as may be suggested by 16S rRNA gene sequences available from public databases), there are organisms that most likely represent new genera, in particular, the strain labelled “*Curtobacterium* sp.” VKM Ac-2058 (AB042093) and some related organisms from plants and plant galls induced by plant parasitic nematodes of the subfamily Anguininae. The bacteria are characterized by the presence of DAB in the cell wall and the major menaquinone MK-11 (L. I. Evtushenko and M. Takeuchi, unpublished observation).

Microbacteriaceae from Low Temperature Environments

Recent data demonstrate that many bacteria of the family Microbacteriaceae occur in frozen condition in different environments. Such bacteria were probably active in natural habitats many (500–3000) years ago and survived frozen until isolation. Some of them may be attributed to the current genera on the basis of 16S rDNA sequence analyses, while others represent separate lines of descent and undoubtedly belong to new undescribed genera. The bacteria “*Cryocola antiquus*,” preliminarily assigned to the genus *Cryobacterium* sp. (Karasev et al., 1998; Kochkina et al., 2001), were isolated from a sample of permafrost sediments 23 m deep, recovered from the frozen (mean annual temperature -12°C) late Pliocene layer (1.8–3 million years old) in the Kolyma Lowland, East Siberia, Russia. The bacteria form yellow or white, round, glistening, opaque colonies. Optimum growth temperature is $18-20^{\circ}\text{C}$, and no growth occurs at 28°C . Cells are aerobic, catalase- and oxidase-positive, nonsporeforming, long irregular rods ($0.4 \times 3.5 \mu\text{m}$), which fragment into shorter motile cells. Cell wall peptidoglycan contains DAB, alanine, glycine, and glutamic acid in the molar ratio consistent with B2 γ type peptidoglycan (Schleifer and Kandler, 1972). Cell wall sugars include rhamnose, which is predominant in amount. The major isoprenoid quinones are MK-11 and MK-12, and the major fatty acids are anteiso-15:0, anteiso-17:0 and iso-16:0. The DNA G+C content is approximately 65 mol%. The phylogenetic analyses based on 16S rDNA sequences indicated that the strains are clustered together with the genus *Cryobacterium psychrophilum* with an 85% bootstrap confidence level and exhibit 96.3–96.6% 16S rDNA binary sequence similarity to this species. However, the permafrost bacteria are clearly distinguished phenotypically from *Cryobacterium psychrophilum*, which is pink-colored, non-motile, does not grow at 18°C , has the major menaquinone MK-10, and produces 12-methyltetradecenoic fatty acid in significant amounts (Suzsuki et al., 1996). Phenotypically, “*Cryocola antiquus*” strains resemble some species of the genus *Leifsonia*; however, the 16S rRNA gene sequence similarities between “*Cryocola antiquus*” and most species of *Leifsonia* are 95.5–96.0%, the exception being *Leifsonia poae* with 97.1% similarity (Gavrish et al., 2003). The phylogenetic and phenotypic data evidently demonstrate that the strains labelled “*Cryocola antiquus*” cannot be assigned unambiguously to either of these genera and should be described as a new genus. Several other bacteria, e.g., strains G50-TB8 (AF479355) and G200-C11

(AF479342), representing a separate line of descent within the family Microbacteriaceae or grouped together with other uncertain bacteria were recovered from 50- to 200-year-old glacial ice from various geographic locations (Christner, 2002).

Recently, Sheridan et al. (2003) has validly described the new genus and species *Rhodoglubus vestalii* to accommodate a psychrophilic, red-pigmented strain LV3^T (=ATCC BAA-534^T =CIP 107482^T; AJ459101) isolated from Antarctic Dry Valley Lake near the McMurdo Ice Shelf. The strain had an optimal growth temperature of 18°C and grew on a variety of media between –2 and 21°C. Scanning electron micrographs revealed small rods with unusual bulbous protuberances in all phases of growth. The strain reportedly has ornithine in the cell wall and the major menaquinones MK-11 and MK-12. The predominant fatty acids were anteiso-C_{15:0}, iso-C_{16:0} and anteiso-C_{17:0}; cells grown at –2°C contained significant amounts of anteiso-C_{15:1}. Phylogenetic analysis of the 16S rRNA gene sequence indicated that *Rhodoglubus vestalii* was related to, but distinct from, organisms of the genera *Agreia*, *Leifsonia* and *Subtercola*. Alignments of 16S rRNA sequences showed that the sequence of *Rhodoglubus vestalii* LV3^T contained a 13 bp insertion that was found in only a few related sequences. The G+C content of DNA was approximately 62 mol%. (Sheridan et al., 2003).

Two other psychrophilic strains from Antarctica, CMS 76r^T (=DSM 15304^T =CIP 107783^T; AJ438585) and CMS 81y^T (DSM 15303^T =CIP 107785^T; AJ438586), have recently been isolated from a cyanobacterial mat sample from a pond in Wright Valley, McMurdo. The strains were curved, non-motile, and catalase-positive rods. They had DL-2,4-diaminobutyric acid in the cell wall, the major menaquinone MK-11, high amounts of anteiso- and iso-branched fatty acids, and a DNA G+C content of 64–66 mol%. The strains differed from one another in many phenotypic characteristics and exhibited 30% DNA relatedness, thus indicating that they represent two different species (Reddy et al., 2003). Unaware of the description of the genus *Rhodoglubus* (Sheridan et al., 2003), Reddy et al. (2003) have described these strains, which are phylogenetically closely related to *Rhodoglubus*, as novel species of the genus *Leifsonia*, *Leifsonia rubra* and *Leifsonia aurea*.

Copiotrophic Ultramicrobacteria and Related Organisms

Extremely small bacteria, called “ultramicrobacteria,” “nanobacteria,” and “picobacteria,” exist

in several taxonomic groups of parasites or pathogens and are known to come from a wide variety of natural environments (Koch, 1996). Iizuka et al. (1998) described the 0.45-μm filtered, free-living, aerobic copiotrophic ultramicrobacteria of the family Microbacteriaceae from urbane soil, some of which are members of the genus *Microbacterium* while others are phylogenetically distant from all known genera of the family. The average cell volume of bacteria, as measured by scanning electron microscope and epifluorescent microscopy with image analysis, was less than 0.3 μm³ at any growth stage. They have menaquinones MK-11 and MK-12 and varied in colony pigmentation (cream to yellow), cell size, doubling time, motility, catalase reaction, protease activity, nitrate reduction, and acid production from glucose. In addition, cells of strain 12-8 (AB008510) were divided by multiple longitudinal and transverse septa that resulted in formation of cells of different size and shape. Such multiseptation of cells is typical of some actinobacteria, e.g., *Blastococcus* (Ahrens and Moll, 1970), *Geodermatophilus* (Luedemann, 1968; Urzi et al., 2001), *Modestobacter* (Mevs et al., 2000), and some others, but was not reported for organisms of the family Microbacteriaceae previously. No phenotypic data are available for the copiotrophic strain 121 (AB008511), which is grouped together with the recently described psychrophilic bacteria *Rhodoglubus vestalii* (Sheridan et al., 2003), *Leifsonia rubra* and *Leifsonia aurea* (Reddy et al., 2003) into a separate phylogenetic cluster in the family Microbacteriaceae.

Small cell size (ca. 0.2–0.4 μm in diameter and 0.6–2 μm in length), which is consistent with the cell volume <0.3 μm³, is typical of cells in cultures of a number of species in the family Microbacteriaceae, e.g., in the genera *Agromyces* (Casida, 1977), *Frigoribacterium* (Kämpfer et al., 2000), *Leifsonia* (Davis et al., 1984b; Suzuki et al., 1999), *Microbacterium* (Iizuka et al. 1998), *Mycetocola* (Tsukamoto et al., 2001), and *Subtercola* (Männistö et al., 2000). Such cell size in culture suggests that they may pass through a 0.45-μm membrane filter and be observed among ultramicro-size bacteria *in situ*.

Microbacteriaceae from Freshwater Ecosystems and Marine Bacterioplankton

Members of the class Actinobacteria, including ultramicro-size representatives of Microbacteriaceae, widely occur in marine and freshwater ecosystems (Hiorns et al., 1997; Takami et al., 1997; Fritz et al., 2000; Methe et al., 1998; Pernthaler et al., 1998; Pernthaler et al., 2001; Zwart et al., 1998; Zwart et al., 2002; Crump et al., 1999;

Rappe et al., 1999; Glöckner et al., 2000; Männistö et al., 2000; Hahn et al., 2003). Broad distribution, abundance, and high biomass of actinobacteria in limnic ecosystems were demonstrated using a combination of phylogenetic analyses and the fluorescence in situ hybridization (FISH) technique (Glöckner et al., 2000). Amount of actinobacteria in fresh water habitats can be comparable with that of β -Proteobacteria and even can become a dominant fraction. These two groups were suggested to inhabit separate functional niches: β -Proteobacteria are able to rapidly utilize the main annual input, whereas the actinobacterial group more efficiently consumes the lower levels of organic carbon at low temperature (Glöckner et al., 2000). Many actinobacterial clones obtained from freshwater habitats, e.g., CRE-FL60 (AF141476; Crump et al., 1999), FukuN101 (AJ289982; Glöckner et al., 2000); PRD01a002B (AF289150; Zwart et al., 2002), represent phylogenetically distant lineages that most likely correspond to separate undescribed genera of the family Microbacteriaceae. A number of isolated strains of the freshwater Microbacteriaceae lineages are ultramicro-size bacteria (cell volume, $<0.1 \mu\text{m}^3$; Hahn et al., 2003). Yellow-pigmented ultramicrobacteria with close 16S rRNA gene sequences (99.4–100%) were obtained from lakes that are ecologically different and geographically separated by great distances. They have clearly different ecophysiological and phenotypic traits and are distinguished by colony morphologies, growth rates, and temperature optima. The strains have a typical Gram-positive cell wall architecture, but the overall shape of cells is unusual for Microbacteriaceae: selenoid, and occasionally cells form rings when no dissociation occurs after the septum is formed. The cell width of strain MWH-Ta1 (AJ507466), a representative of yellow-pigmented isolates, generally ranged from 154.2 to 244.4 nm. The red-pigmented strain MWH-Ta3 (AJ507468) has markedly larger cells and exhibits levels of 16S rRNA similarity of 94.5% to the yellow-pigmented bacteria. Predator-prey experiments showed that at least one of the ultramicro-size isolates is protected against predation by the bacterivorous nanoflagellate *Ochromonas* sp. (Hahn et al., 2003). The finding that members of the class Actinobacteria are abundant in freshwater ecosystems is quite intriguing in the light of the general perception that this group including Microbacteriaceae is typical for terrestrial environments and less common in aquatic ecosystems (Williams et al., 1984; Madigan et al., 1997). Further studies of Microbacteriaceae from freshwater and marine habitats will discover additional diversity of Microbacteriaceae and may provide an opportunity to gain more

insight into the evolutionary process of terrestrial and aquatic actinobacteria.

The Genus *Nocardioides*

JUNG-HOON YOON AND YONG-HA PARK

The genus *Nocardioides* was proposed by Prauser (1976) for Gram-positive, non-acid-fast, aerobic, and mesophilic nocardioform actinomycetes, developing a mycelium that fragments into irregular rod- to coccus-like elements. Originally, the genus contained two species, i.e., *Nocardioides albus* and *Nocardioides luteus* (Prauser, 1984), both forming well-developed mycelia. The primary mycelium shows abundantly branching hyphae growing on the surface and penetrating into agar media. The hyphae of the aerial mycelium either do not branch or are sparsely and irregularly branched, resembling the structure of the aerial mycelium of nocardiae. Both the primary and the aerial mycelia can break up into short rod-like fragments, which give rise to new mycelia, by extruding one or two hyphae. The inclusion of additional species to the genus *Nocardioides* resulted in the morphologic heterogeneity of the genus. Other species subsequently transferred to *Nocardioides* were *Arthrobacter simplex* (O'Donnell et al., 1982) and *Pimelobacter jensenii* (Suzuki and Komagata, 1983). The genus *Pimelobacter* was originally proposed by Suzuki and Komagata (1983) for *Arthrobacter* species with LL-2,6-diaminopimelic acid in the peptidoglycan. Three *Pimelobacter* species were recognized, namely, *P. jensenii* (previously regarded as an atypical strain of *Arthrobacter simplex*), *P. tumescens* (previously, type strain of *Arthrobacter tumescens*), and *P. simplex* (previously regarded as the type strain of *Arthrobacter simplex* and two strains of “*Brevibacterium lipolyticum*”). As a consequence of a taxonomic reevaluation (Collins et al., 1989b), *Pimelobacter jensenii* was transferred to the genus *Nocardioides* as *N. jensenii*, and *P. tumescens* was reclassified in a new genus, *Terrabacter*, as *T. tumescens* (Collins et al., 1989b). The reclassified *N. simplex* and *N. jensenii* are coryneform actinomycetes that form neither a primary mycelium nor an aerial mycelium.

The number of species belonging to the genus *Nocardioides* has continuously increased. Two more coryneform species, *Nocardioides fastidiosa* (Collins and Stackebrandt, 1989a) and

Nocardioides plantarum (Collins et al., 1994), were isolated from herbage. *Nocardioides fastidiosa* has MK-9(H₄) as the predominant menaquinone. Consistent with this, the genus *Nocardioides* was known to have MK-8(H₄) or MK-9(H₄) as the predominant menaquinone; however, Tamura and Yokota (1994) subsequently transferred *N. fastidiosa* to the genus *Aeromicrobium* as *A. fastidiosum*. Later, three more *Nocardioides* species, *N. pyridinoliticus*, *N. nitrophenolicus* and *N. aquaticus*, were added to the genus. Strains of these species form neither a primary mycelium nor an aerial mycelium.

Currently, there are eight validly described *Nocardioides* species, namely, *N. albus* (Prauser, 1976), *N. aquaticus* (Lawson et al., 2000), *N. jensenii* (Suzuki and Komagata, 1983; Collins et al., 1989b), *N. luteus* (Prauser, 1984), *N. nitrophenolicus* (Yoon et al., 1999), *N. plantarum* (Collins et al., 1994), *N. pyridinoliticus* (Yoon et al., 1997c), and *N. simplex* (O'Donnell et al., 1982). In addition, there are three invalidly described species, namely, “*N. flavus*” (Ruan and Zhang, 1979), “*N. fulvus*” (Ruan and Zhang, 1979), and “*N. thermolilacinus*” (Lu and Yan, 1983). The type strain of “*N. flavus*” was previously assumed to be a synonym of *N. luteus* (Prauser, 1989). Furthermore, the type strains of “*N. flavus*” and “*N. fulvus*” showed 16S rDNA similarity values of 100% with the type strain of *N. luteus* (Yoon et al., 1998b). Two strains of “*N. thermolilacinus*” were considered to be streptomycetes since they exhibit a *Streptomyces*-like life cycle and are susceptible to *Streptomyces* phages, but not to *Nocardioides* phages (Prauser, 1989). Analysis of 16S rDNA sequence also showed that “*N. thermolilacinus*” is most closely related to the genus *Streptomyces* (Yoon et al., 1998b).

The cell wall peptidoglycan of *Nocardioides* strains is defined by LL-2,6-diaminopimelic acid and glycine (wall chemotype I sensu, Lechevalier and Lechevalier, 1970) and a lack of mycolic acids (Prauser, 1976). The cellular fatty acid profile is complex, containing *iso*- and *anteiso*-branched, straight chain, unsaturated, and 10-methyl fatty acids. The major component is 14-methyl pentadecanoic acid (*iso*-C_{16:0})

(O'Donnell et al., 1982; Miller et al., 1991; Park et al., 1999). The predominant isoprenoid quinone is a tetrahydrogenated menaquinone with eight isoprene units (MK-8[H₄]; O'Donnell et al., 1982; Tamura and Yokota, 1994; Yoon et al., 1997c; Yoon et al., 1999). The G+C content of the DNA is 67–74 mol%. Phylogenetic analyses based on 16S rDNA sequences show that the genus *Nocardioides* is included as the type genus in the family Nocardioideaceae, which also includes the genera *Actinopolymorpha*, *Aeromicrobium*, *Kribbella*, *Hongia* and *Marmoricola* (Miller et al., 1991; Stackebrandt et al., 1997; Yoon et al., 1998b; Park et al., 1999; Lee et al., 2000; Urzì et al., 2000; Wang et al., 2001). The type species of the genus *Nocardioides* is *N. albus* (Prauser, 1976).

Habitats

Members of the genus *Nocardioides* have been isolated from a variety of habitats, including soils, herbage, an oil shale column, industrial wastewater, and water of hyper-saline lakes. *Nocardioides albus* is widely distributed in soil (see Prauser, 1976 and Prauser, 1989) and has been isolated from a variety of soils from different parts of the world (Prauser, 1976). *Nocardioides luteus* was isolated from soils of subtropical regions (Tille et al., 1978; Prauser, 1984). Strains identified as *N. simplex* have also been isolated from a variety of soils: the type strain of *N. simplex* was isolated from rice soil (Jensen, 1934) and other strains from the soil of the petroleum zone in Japan (Iizuka and Komagata, 1964). More recently, *Nocardioides* strains have been isolated from other sources. *Nocardioides plantarum* was isolated from herbage (Collins et al., 1994). *Nocardioides pyridinolyticus*, which can degrade pyridine, was isolated from the oxic zone of an oil shale column (Yoon et al., 1997c). *Nocardioides nitrophenolicus* was isolated from industrial wastewater in South Korea (Yoon et al., 1999). Recently, *N. aquaticus* was isolated from water of Ekho Lake, a hypersaline, heliothermal and meromictic lake, in the ice-free area of the Vestfold Hills in East Antarctica (Lawson et al., 2000).

Isolation and Cultivation

Nocardioides strains can be isolated by the usual dilution plating technique on solid media suitable for actinomycetes, such as the media by the International Streptomyces Project (Shirling and Gottlieb, 1966), glucose-asparagine agar (Lin-

denbein, 1952), and chitin agar (Prauser, 1976). They generally grow well on other kinds of complex organic media too, such as nutrient agar, trypticase soy agar, and YM agar. No selective media or enrichment procedures have yet been described which are specific for organisms of this genus. *Nocardioides* strains grow on a wide range of media. Most *Nocardioides* strains were isolated between 25 and 30°C, but *N. aquaticus* was isolated at 15°C and its optimal temperature for growth is 16–26°C.

Nocardioides albus strains were isolated by using the agar double-layer method, in which dilutions of soil suspensions are mixed into the melted agar, which is then used for the upper layer (Prauser, 1976). The isolation media were commonly used types, such as inorganic salt-starch agar (Gause et al., 1957), arginine-glycerol-salt agar (El-Nakeeb and Lechevalier, 1963), and dilute oatmeal agar (Prauser, 1976). *Nocardioides simplex* strains have been isolated by using different media. The type strain was isolated on asparagine agar (Jensen, 1934), and two other strains previously classified as members of “*Brevibacterium lipolyticum*” were isolated on kerosene medium and on crude oil medium (Iizuka and Komagata, 1964). *Nocardioides plantarum* was isolated and routinely cultivated on EYPB medium (Cure and Keddie, 1973; Collins et al., 1994). *Nocardioides pyridinolyticus* was isolated on minimal salts medium (Lee et al., 1994) containing 0.1% (v/v) pyridine and 0.4% (w/v) glucose. *Nocardioides nitrophenolicus* was isolated on modified minimal salts medium (Cho et al., 1998b; Yoon et al., 1999) supplemented with *p*-nitrophenol (100 mg/liter) as a source of carbon, nitrogen and energy. The most recently described species, *N. aquaticus*, was isolated on oligotrophic PYGV medium (Staley, 1968) prepared with water taken 1 m below the surface of the Antarctic Lake where it was discovered and was cultivated on PYGV medium prepared with artificial seawater (ASW; Lyman and Fleming, 1940). A variety of procedures, using contact plates, sterile cotton swabs, and porous plastic plugs, was used to isolate heterotrophic bacteria from Spanish caves with Paleolithic rock art, and these showed the existence of a *Nocardioides* isolate (Groth et al., 1999). A new method was elaborated for the selective isolation of actinomycetes from soil, which involves the pre-treatment of soil samples with electric pulses (Bulina et al., 1998). Treatment with 3-ms pulses at a field intensity of 12 kV/cm² resulted in a significant increase (threefold on average) in the proportion of rare actinomycetes isolated. Interestingly, treatment at a field intensity of 16 kV/cm² resulted in highly selective isolation of representatives of the genus *Nocardioides* (Bulina et al., 1998).

Media for Isolation and Cultivation

The following are the recipes for the media mentioned above that are not commercially available.

Arginine-glycerol-salt Agar (El-Nakeeb and Lechevalier, 1963)

Arginine monohydrochloride	1.0 g
Glycerol	12.5 g
K ₂ HPO ₄ (anhyd.)	1.0 g
NaCl	1.0 g
MgSO ₄ · 7H ₂ O	0.5 g
Fe ₂ (SO ₄) ₃ · 6H ₂ O	0.01 g
CuSO ₄ · 5H ₂ O	0.001 g
ZnSO ₄ · 7H ₂ O	0.001 g
MnSO ₄ · H ₂ O	0.001 g
Agar	15.0 g
Distilled water	1 liter

Adjust pH to 6.9–7.1

Asparagine Agar (Jensen, 1934)

Dextrose	10.0 g
Asparagine	1.0 g
K ₂ HPO ₄ (anhyd.)	1.0 g
MgSO ₄ (anhyd.)	0.5 g
NaCl	0.5 g
Agar	20.0 g
Distilled water	1 liter

Adjust pH to 7.0–7.2

Chitin Agar (Prauser, 1976)

KCl	0.5 g
K ₂ HPO ₄ (anhyd.)	1.0 g
MgSO ₄ (anhyd.)	0.5 g
FeSO ₄ (anhyd.)	0.01 g
Chitin	1.0 g
Agar	15.0 g
Distilled water	1 liter

Adjust pH to 7.0

Crude Oil Medium (Iizuka and Komagata, 1964)

Crude oil	10.0 g
NH ₄ NO ₃	2.5 g
Na ₂ HPO ₄ (anhyd.)	1.0 g
KH ₂ PO ₄ (anhyd.)	0.5 g
MgSO ₄ · 7H ₂ O	0.5 g
MnCl ₂ · 4H ₂ O	0.2 g
CaCO ₃ (anhyd.)	5.0 g
CaCl ₂ (anhyd.)	trace
ZnSO ₄ · 7H ₂ O	trace
FeSO ₄ · 7H ₂ O	trace
Agar	15.0 g
Distilled water	1 liter

Adjust pH to 7.2 before sterilization. CaCO₃ is added after sterilization.

Dilute Oatmeal Agar (Prauser, 1976)

Oatmeal	3.0 g
KNO ₃	0.2 g
K ₂ HPO ₄ (anhyd.)	0.5 g
MgSO ₄ (anhyd.)	0.2 g
Agar	15.0 g
Distilled water	1 liter

Adjust pH to 7.0

Glucose-asparagine Agar (Lindenbein, 1952)

Glucose	10.0 g
L-Asparagine	0.5 g
K ₂ HPO ₄ (anhyd.)	0.5 g
Agar	20.0 g
Distilled water	1 liter

Adjust pH to 6.8–7.0

Glycerol-asparagine Agar (ISP medium 5; Pridham and Lyons, 1961)

L-Asparagine	1.0 g
Glycerol	10.0 g
K ₂ HPO ₄ (anhyd.)	1.0 g
Trace salts solution (see below)	1.0 ml
Agar	20.0 g
Distilled water	1 liter

Adjust pH to 7.0–7.4

Trace Salts Solution

FeSO ₄ · 7H ₂ O	0.1 g
MnCl ₂ · 4H ₂ O	0.1 g
ZnSO ₄ · 7H ₂ O	0.1 g
Distilled water	100 ml

Inorganic Salts-starch Agar (ISP Medium 4; Gause et al., 1957)

Soluble starch	10.0 g
K ₂ HPO ₄ (anhyd.)	1.0 g
MgSO ₄ · 7H ₂ O	1.0 g
NaCl	1.0 g
(NH ₄) ₂ SO ₄ (anhyd.)	2.0 g
CaCO ₃ (anhyd.)	2.0 g
Trace salts solution (see below)	1.0 ml
Agar	20.0 g
Distilled water	1 liter

Adjust pH to 7.0–7.4

Trace Salts Solution

FeSO ₄ · 7H ₂ O	0.1 g
MnCl ₂ · 4H ₂ O	0.1 g
ZnSO ₄ · 7H ₂ O	0.1 g
Distilled water	100 ml

Kerosene Medium (Iizuka and Komagata, 1964)

Kerosene	10.0 g
NH ₄ Cl	2.0 g
Na ₂ HPO ₄ (anhyd.)	1.0 g
KH ₂ PO ₄ (anhyd.)	0.5 g
MgSO ₄ · 7H ₂ O	0.5 g
NaCl	2.0 g
Agar	15.0 g
Distilled water	1 liter

Adjust pH to 7.2 before sterilization.

Minimal Salts Medium (Lee et al., 1991)

K ₂ HPO ₄ (anhyd.)	1.0 g
KCl	0.25 g
MgSO ₄ · 7H ₂ O	0.25 g
Trace element solution (see below)	1.0 ml
Agar	15 g
Distilled water	1 liter

Adjust pH to 7.2

Trace Element Solution

FeSO ₄ · 7H ₂ O	4.0 mg
MnSO ₄ · H ₂ O	4.0 mg
Na ₂ MoO ₄ (anhyd.)	0.5 mg
CaCl ₂ · H ₂ O	50 mg
NaCl	100 mg
Distilled water	100 ml

Modified Minimal Salts Medium (Cho et al., 1998a; Yoon et al., 1999)

K ₂ HPO ₄ (anhyd.)	1.0 g
NaH ₂ PO ₄ · 2H ₂ O	0.5 g
KCl	0.25 g
MgSO ₄ · 7H ₂ O	0.25 g
Trace element solution (see below)	1.0 ml
Agar	15 g
Distilled water	1 liter

Adjust pH to 7.2

Trace Element Solution

FeSO ₄ · 7H ₂ O	4.0 mg
MnSO ₄ · H ₂ O	4.0 mg
Na ₂ MoO ₄ (anhyd.)	0.5 mg
CaCl ₂ · H ₂ O	50 mg
NaCl	100 mg
Distilled water	100 ml

PYGV Marine Medium (Staley, 1968)

Peptone	0.25 g
Yeast extract	0.25 g
Mineral salt solution (see below)	20.0 ml
Glucose solution (2.5%)	10.0 ml
Vitamin solution (see below)	10.0 ml
Agar	15 g
(Artificial) seawater	960 ml

Mix thoroughly all components, except the glucose and vitamin solutions. After autoclaving and cooling, add aseptically filter-sterilized glucose and vitamin solutions. Adjust pH to 7.5 with sterile KOH, if necessary.

Mineral Salt Solution

MgSO ₄ · 7H ₂ O	29.7 g
Nitritotriacetic acid	10.0 g
CaCl ₂ · 2H ₂ O	3.34 g
FeSO ₄ · 7H ₂ O	99.0 mg
Na ₂ MoO ₄ · 2H ₂ O	13.0 mg
Metals 44 (see below)	50.0 ml
Distilled water	950 ml

Add nitritotriacetic acid to 500 ml of distilled water. Dissolve by adjusting pH to 6.5 with KOH. Add remaining components and distilled water. Readjust pH to 7.2.

Vitamin Solution

Biotin	2.0 mg
Folic acid	2.0 mg
Pyridoxine · HCl	10.0 mg
Riboflavin	5.0 mg
Thiamine × HCl	5.0 mg
Nicotinamide	5.0 mg
Calcium pantothenate	5.0 mg
Cyanocobalamin	0.1 mg
p-Aminobenzoic acid	5.0 mg
Distilled water	1 liter

Metals 44

EDTA	250.0 mg
ZnSO ₄ · 7H ₂ O	1095.0 mg
FeSO ₄ · 7H ₂ O	500.0 mg
MnSO ₄ · H ₂ O	154.0 mg
CuSO ₄ · 5H ₂ O	39.2 mg
Co(NO ₃) ₂ · 6H ₂ O	24.8 mg
Na ₂ B ₄ O ₇ · 10H ₂ O	17.7 mg
Distilled water	100 ml

Yeast Extract-malt Extract Agar (ISP Medium 2)

Yeast extract	4.0 g
Malt extract	10.0 g
Glucose	4.0 g
Agar	20.0 g
Distilled water	1 liter
Adjust pH to 7.3	

Preservation

For short-term preservation, serial transfer from agar slants of appropriate media is recommended. Agar slants can be kept at 4°C for at least 2 months. For long-term preservation, lyophilization and storage in liquid nitrogen or in frozen glycerol suspensions are suitable. For lyophilization, the cell mass is suspended in an appropriate fluid, such as 20% (w/v) skim milk. For storage in liquid nitrogen, the cell mass is inoculated into cryo-tubes containing an appropriate fluid, such as 20% glycerol. Glycerol suspension is prepared by suspending the cell mass in aqueous glycerol in the appropriate vial or tube. The vial or tube is stored at -20 or -70°C.

Identification

Members of the genus *Nocardioidea* can be distinguished from all other actinomycetes by using a combination of chemical properties and phylogenetic analysis based on 16S rRNA gene sequences. However, within this genus, morphological features vary greatly and may be insufficient to differentiate it reliably from other genera of the family Nocardioideaceae or from other actinomycetes.

Morphology

Nocardioidea albus and *N. luteus* form well-developed mycelia (Prauser, 1976; Prauser, 1984). The hyphae of the primary mycelium, 0.5–0.8 µm in diameter, grow on the surface or penetrate into agar media, branch abundantly, and are irregularly septated. Fragmentation of the hyphae begins in the old parts of the colonies, and as it proceeds, additional cross-walls are formed. The hyphae of the aerial mycelium, 0.6–

1.0 μm in diameter, either do not branch or are sparsely and irregularly branched, thus resembling those of nocardiae (Fig. 1). The aerial hyphae break up into rod- or coccus-like fragments, which are more regular than those of the primary mycelium. The fragments of both the primary and the aerial mycelia give rise to new mycelia by extruding new hyphae. Other *Nocardioides* species, namely, *N. simplex*, *N. jensenii*, *N. plantarum*, *N. pyridinolyticus*, *N. nitrophenolicus* and *N. aquaticus*, form neither primary mycelium nor aerial mycelium. The cells of *Nocardioides* species, which form no mycelia, are rods or cocci. These cells show rod-to-coccus morphogenesis from the early exponential growth phase to the stationary growth phase. Figure 2 shows this rod-to-coccus morphogenesis of *N. pyridinolyticus* KCTC 0074BP^T as the culture ages. Cells of *N. simplex* and *N. jensenii* are irregularly rod-shaped in the early phase of growth and coccoid in old cultures. After 1 day of cultivation on YM agar, the cells of the type strains are $1.0\text{--}1.2 \times 1.5\text{--}6.0 \mu\text{m}$ and $0.6\text{--}0.8 \times 3.0\text{--}7.0 \mu\text{m}$, respectively. Cells of *N. plantarum* are short rods or cocci. Cells of *N. pyridinolyticus* are $0.5\text{--}0.6 \mu\text{m}$ wide and $1.2\text{--}1.6 \mu\text{m}$ long in the expo-

nential phase of growth. Cells of *N. nitrophenolicus* are $0.5\text{--}0.8 \mu\text{m}$ wide and $1.0\text{--}3.0 \mu\text{m}$ long in the exponential phase of growth. Cells of *N. aquaticus* are cocci or short rods, measuring $0.9\text{--}1.0 \mu\text{m}$ in diameter in old cultures. Cells either

A) Early growth phase (3-d cultivation on nutrient agar); B) stationary growth phase (7-d cultivation on nutrient agar); and C) early growth phase (3-d cultivation on nutrient agar).

are nonmotile or possess a single polar flagellum. The flagellum of *N. pyridinolyticus* KCTC 0074BP^T is shown in Fig. 2.

Colonies of *N. albus* and *N. luteus* appear 1 or 2 days after incubation at 28°C and develop relatively quickly. The primary mycelium of *N. albus* is white, whitish, to faintly cream-colored on oatmeal agar, yeast extract-malt extract agar, glucose-asparagine agar and other agars; in aged cultures, it is whitish to faintly brownish. The aerial mycelium of *N. albus* is thin, dense and chalky. Colonies lacking an aerial mycelium appear pasty, smooth to wrinkled and dull to bright. The aerial mycelium may cover the primary mycelium totally, may be produced only in patches or at the margins of colonies, or may be absent, depending on strain, culture conditions, and the procedures and the duration of maintenance. The formation of aerial mycelium is usually good on yeast extract-malt extract agar, oatmeal agar and glucose-asparagine agar and fair on inorganic salts-starch agar (ISP 4 agar) and glycerol-asparagine agar. On complex organic medium, the aerial mycelium does not form. The colonies do not produce soluble pigments. Faint brownish soluble pigments may occur in aged cultures and reddish brown pigments may occur on media containing tyrosine as sole amino acid. In *N. luteus*, the primary mycelium is yellow on oatmeal agar and other media, varying to orange-yellow in aged cultures. The aerial mycelium on oatmeal agar is thin, dense and cream-colored if well developed, otherwise white. Colonies lacking an aerial mycelium appear pasty, smooth to wrinkled and dull to bright. No soluble pigments are produced, except for a reddish-brown pigment on media containing tyrosine as sole amino acid. Colonies of other *Nocardioide*s species are smooth, glossy and raised or convex. Their colors are creamy, yellowish white or dull orange.

The morphological heterogeneity within the genus *Nocardioide*s makes it difficult to differentiate the genus from others genera of the family Nocardiodaceae, as well as from other actinomycetes. Of the genera belonging to the same family, the genera *Kribbella* and *Hongia* have morphologies similar to those of *N. albus* and *N. luteus*; the genera *Aeromicrobium* and *Marmoricola* have morphologies similar to those of other *Nocardioide*s species. The genus *Marmoricola* shows no rod/coccus life cycle.

Chemotaxonomy

The genus *Nocardioide*s is easily differentiated from all other actinomycetes on the basis of the diaminopimelic acid type in the cell wall peptidoglycan, menaquinone profile, and the cellular

fatty acid profile (Park et al., 1999; Wang et al., 2001; Table 1). The genus *Nocardioide*s is one of a few genera that have LL-2,6-diaminopimelic acid (LL-DAP) as the diagnostic diamino acid in the cell wall peptidoglycan (Prauser, 1976). This feature, together with glycine in the cell wall peptidoglycan, indicates that this genus is wall chemotype I (Lechevalier and Lechevalier, 1970). This chemical marker distinguishes the genus *Nocardioide*s from many other actinomycete genera that possess other types of diamino acids in the cell wall peptidoglycan. Fewer than 20 validly described genera contain LL-DAP in the cell wall peptidoglycan (Maszenan et al., 1999; Lee et al., 2000; Urzì et al., 2000; Yoon and Park, 2000; Wang et al., 2001). The genus *Nocardioide*s can be distinguished from most of these on the basis of menaquinone profile (Table 2). The genus *Nocardioide*s contains tetrahydrogenated menaquinone with eight isoprenoid units (MK-[8H₄]) as the predominant menaquinone, a characteristic shared, along with LL-DAP in the cell wall, only with the genera *Marmoricola* (Urzì et al., 2000), *Terrabacter* (Collins et al., 1989b), and *Terracoccus* (Prauser et al., 1997). The genus *Nocardioide*s can be differentiated from these by cellular fatty acid profile.

The cellular fatty acid profiles of *Nocardioide*s species are similar, containing *iso*- and *anteiso*-branched, straight chain, unsaturated, and 10-methyl fatty acids (O'Donnell et al., 1982; Miller et al., 1991; Park et al., 1999). The major fatty acid characterizing the genus is *iso*-C_{16:0} (14-methyl pentadecanoic acid). This profile clearly distinguishes it from the genera *Marmoricola*, *Terrabacter* and *Terracoccus*. The *Marmoricola* profile is characterized by the presence of C_{16:0} and C_{18:1} (Urzì et al., 2000). The *Terracoccus* profile has *iso*-C_{15:0} and *anteiso*-C_{15:0} as the major fatty acids (Prauser et al., 1997). The genus *Terrabacter* has shown slightly varying results. O'Donnell et al. (1982) and Park et al. (1999) concluded that major fatty acids are C_{18:1}, C_{16:0} and *iso*-C_{15:0}; Miller et al. (1991) concluded they are *anteiso*-C_{15:0}, C_{18:1} and C_{17:1}; Schumann et al. (1997) concluded they are *iso*-C_{15:0} and *iso*-C_{14:0}. These differences may be due to differences in cultivation conditions and in preparation methods. The genera *Terrabacter* and *Terracoccus* have been shown to be phylogenetically distantly related to other members of the family Nocardiodaceae (Prauser et al., 1997; Yoon et al., 1998b; Fig. 3).

The phospholipid profiles of *Nocardioide*s species are variable. All species so far studied contain phosphatidylglycerol, diphosphatidylglycerol, and other unidentified phospholipids (O'Donnell et al., 1982; Collins et al., 1989b; Lawson et al., 2000). Phosphatidylinositol is

Data taken from Collins et al. (1989b); Collins et al. (1994); Lawson et al. (2000); Prauser (1976); Prauser (1984); Prauser (1989); Suzuki and Komagata (1983); Yoon et al. (1997); Yoon et al. (1999).

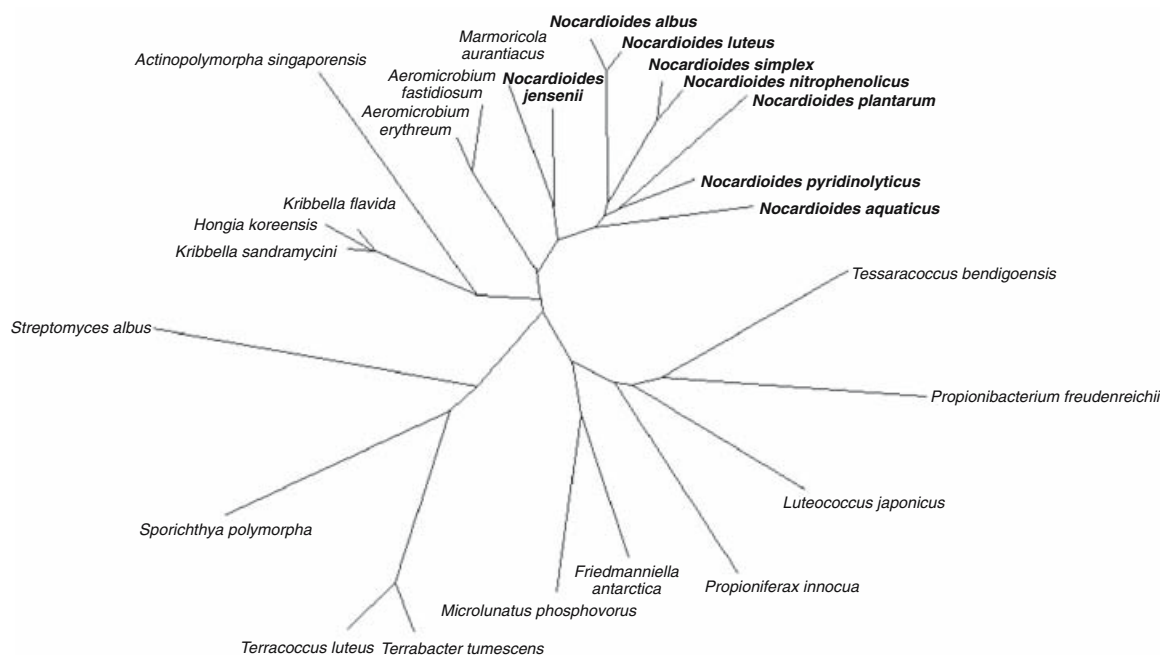

Fig. 3. Phylogenetic tree based on 16S rRNA gene sequences showing the positions of *Nocardioides* species and the representatives of other related taxa. Scale bar represents 0.01 substitutions per nucleotide position.

variably present in *Nocardioides* species. *Nocardioides jensenii* and *N. aquaticus* contain phosphatidylinositol, but *N. albus* and *N. simplex* do not. *Nocardioides albus*, *N. jensenii* and *N. simplex* contain phosphatidylglycerol containing 2-hydroxy fatty acids. Polyamines were analyzed for classification of coryne- and nocardioform actinomycetes with LL-DAP, including five *Nocardioides* species (Busse and Schumann, 1999). Most *Nocardioides* strains have high concentrations of the diamines putrescine and cadaverine (Busse and Schumann, 1999). This similarity is consistent with the phylogenetic homogeneity of *Nocardioides* species (Yoon et al., 1998b). The type strain of *N. plantarum* was found to contain a relatively low concentration of polyamine, and the predominant diamine was cadaverine. When two strains of *N. albus* (IMET 7807^T and IMET 7815) were grown on a mineral medium (Lindenbein, 1952), cadaverine was again the predominant component. Most strains of the genus *Nocardioides*, when grown in R medium, contain high concentration of putrescine in addition to cadaverine, and this can differentiate them from the genus *Aeromicrobium*.

Molecular Systematics

The DNA G+C content of *Nocardioides* species is 67–74 mol% as determined from the thermal

denaturation (T_m) method of Garvie (1978) and Marmur and Doty (1962) or the HPLC method of Tamaoka and Komagata (Tamaoka and Komagata, 1984; Tables 1 and 2). The 16S rRNA gene sequences have been determined for all *Nocardioides* species (Collins et al., 1989b; Collins et al., 1994; Yoon et al., 1998b; Lawson et al., 2000). Levels of nucleotide similarity are 93.5–99.0%. Intraspecific phylogenetic relationships based on 16S rRNA gene sequence similarities have been studied in *N. albus* and *N. simplex* (Yoon et al., 1998b). For 18 strains assigned to *N. albus*, the mean nucleotide similarity is $99.5 \pm 0.5\%$ (Yoon et al., 1998b). For *N. simplex*, eight strains have been investigated. Five strains, including the type strain, share an identical 16S rDNA sequence (Yoon et al., 1998b). However, the other three strains (ATCC 13260, 19565, and 19566) exhibited only 90.2–90.7% 16S rDNA similarity to the five closely related *N. simplex* strains and 89.9–92.2% similarity with the type strains of other *Nocardioides* species (Yoon et al., 1998b). These three strains are more related to the genus *Rhodococcus*, especially *R. erythropolis*, than to the genus *Nocardioides* (Yoon et al., 1998b). The results obtained in chemotaxonomic analysis are consistent with this, and the three strains have hence been reclassified as members of the genus *Rhodococcus* (Yoon et al., 1997a).

Studies of 16S rDNA sequence also showed the exact taxonomic positions of some invalid

*Nocardioide*s species (Yoon et al., 1998b). Two strains (71-N54^T = IFO 14396^T and 71-N82 = IFO 14397; Ruan and Zhang, 1979) assigned to “*N. flavus*” and one strain (71-N86^T = JCM 3335^T; Ruan and Zhang, 1979) assigned to “*N. fulvus*” show 100% nucleotide similarity with *N. luteus*. The type strain (71-N54^T) of “*N. flavus*” was assumed to be a synonym of *N. luteus* by Prauser (1989). However, another strain (65-N86 = IFO 14399) assigned to “*N. fulvus*” shows low-level 16S rRNA gene nucleotide similarity (91.4%) with the type strain of “*N. fulvus*.” It, together with an unclassified *Nocardioide*s sp. ATCC 39419, has been classified as a member of a new genus, *Kribbella* (Park et al., 1999). Two strains (T505^T = IFO 14335^T and T511 = IFO 14336; Lu and Yan, 1983) assigned to “*N. thermophilacinus*” show low levels of 16S rRNA gene similarity (88.9–90.9%) with other members of the genus *Nocardioide*s. Phylogenetic analysis based on 16S rRNA gene sequences reveals that they fall within the radiation of the cluster comprising *Streptomyces* species (Yoon et al., 1998b). These two strains also display a streptomyces-like life cycle and are susceptible to *Streptomyces* phages but not to *Nocardioide*s phages (Prauser, 1989). Therefore, they are regarded as members of the genus *Streptomyces*.

Phylogenetic analysis based on 16S rRNA gene sequences shows that all *Nocardioide*s species, except for *N. jensenii*, form distinct phylogenetic lineages within the radiation of the cluster encompassed by the genus *Nocardioide*s (Fig. 3). *Nocardioide*s *jensenii* was found to form a phylogenetic cluster with *Marmoricola aurantiacus* (Urzi et al., 2000; Fig. 3). The genus *Nocardioide*s forms a distinct monophyletic group within the evolutionary radiation encompassed by the family Nocardioideaceae, which also includes the genera *Actinopolymorpha* (Wang et al., 2001), *Aeromicrobium* (Miller et al., 1991), *Hongia* (Lee et al., 2000), *Kribbella* (Park et al., 1999), and *Marmoricola* (Urzi et al., 2000). Levels of 16S rRNA gene similarity between *Nocardioide*s species and members of other genera belonging to the family Nocardioideaceae are in the range of 89.9–94.3%. Stackebrandt et al. (1997) proposed 16S rRNA gene signature nucleotides characteristic of the family Nocardioideaceae at the following positions: 66-103 (G-C), 328 (C), 370-391 (G-C), 407-435 (A-U), 602-636 (G-U), 658-748 (U-A), 686 (U), 780 (G), 787 (A), 819 (U), 825-875 (G-C), and 1409-1491 (C-G). However, some newly proposed genera within the family have variations at a few of these positions. The genera *Actinopolymorpha*, *Hongia* and *Kribbella* have a C-G pair at positions 370-391 (Wang et al., 2001; Table 1). The genus *Actinopolymorpha* has this plus an A-T pair at positions 602-636 (Wang et al., 2001; Table 1).

Some other genes, such as the 16S-23S rRNA gene's internally transcribed spacer (ITS) region and the ribonuclease P (RNase P) RNA gene, have also been used for elucidating genetic relationships between *Nocardioide*s species and between the genus *Nocardioide*s and other related taxa (Yoon et al., 1998a; Yoon et al., 2000). In 33 strains assigned to the genus *Nocardioide*s, the 16S-23S ITS sequences range from 328 bp to 539 bp. *Nocardioide*s strains contain no tRNA sequences in their 16S-23S ITSs, as shown previously for some actinomycete species (Baylis and Bibb, 1988; Suzuki et al., 1988; Pernodet et al., 1989; Normand et al., 1992; Kim et al., 1993; Yoon et al., 1997b). In the type strains of validly described *Nocardioide*s species, the 16S-23S ITSs are highly divergent in size and sequence. Their lengths range from 328 bp (*N. nitrophenolicus*) to 514 bp (*N. albus*). Between these type strains, the mean nucleotide similarity is $68.1 \pm 16.8\%$, and this is low enough to distinguish between the species. The most distant relationship was between *N. jensenii* and *N. simplex*, for which the nucleotide similarity was 51.3%. Interestingly, the *N. jensenii* sequence was more similar to those of the genera *Aeromicrobium* and *Kribbella* than to those of other *Nocardioide*s species. The 16S-23S ITS of *N. luteus* is only 1 bp different from those of strains 71-N54^T and 71-N82, assigned to “*N. flavus*,” and it is identical to that of “*N. fulvus*” strain 71-N86^T, confirming the close relationship deduced from 16S rDNA sequence analysis. Intraspecific relationships were studied in *N. albus* and *N. simplex* (Yoon et al., 1998a). In 18 strains assigned to *N. albus*, the 16S-23S ITS sequences ranged from 468 bp to 533 bp, and the mean intraspecific nucleotide similarity value was $92.1 \pm 7.9\%$. In *N. simplex* strains, the sequences were 386 bp in all but one strain (NCIMB 12919), which has two types of 16S-23S ITS sequences (387 and 388 bp). The levels of nucleotide similarity range from 97.7 to 100%.

RNase P is a ribonuclease that cleaves the 5' leader sequences of tRNA precursors and is a ribonucleoprotein composed of an RNA molecule of about 400 nucleotides and a protein subunit of about 120 amino acids (Pace and Brown, 1995). RNase P RNA is encoded by a single-copy gene (*rnp B*) in Gram-positive bacteria (Haas et al., 1996) and its size is relatively conserved (350–400 bp in bacteria; Pace and Brown, 1995). Recently, this gene has been evaluated as a new phylogenetic marker (Cho et al., 1998b; Yoon and Park, 2000). RNase P RNA genes have been sequenced to investigate the relationships between the genus *Nocardioide*s and other taxa, as well as the relationships between *Nocardioide*s species (Yoon and Park, 2000). Among validly described *Nocardioide*s species, the

sequences are relatively divergent, when compared with those of 16S rDNA. Among the type strains of those species, the mean level of sequence similarity is $85.8 \pm 8.2\%$, and if gaps are included, it is approximately $76.6 \pm 12.5\%$. The topology of the phylogenetic trees of 16S rRNA gene sequences and RNase P RNA gene sequences (Yoon et al., 1998b; Yoon and Park, 2000) was mostly consistent.

In a phylogenetic analysis based on RNase P RNA gene sequences, the type strains of *N. albus* and *N. luteus* are phylogenetic neighbors, with nucleotide similarity of 94%. The type strain (71-N54^T) of "*N. flavus*" has a sequence identical to that of *N. luteus*. The type strain (71-N86^T) of "*N. fulvus*" differs from *N. luteus* by only one base pair. This supports previous data showing that two strains assigned to "*N. flavus*" and one strain assigned to "*N. fulvus*" could be classified as members of *N. luteus*. *Nocardioide*s *simplex* forms the closest phylogenetic cluster with *N. nitrophenolicus*, and the nucleotide similarity between their type strains is 94.7%. Other *Nocardioide*s species, *N. jensenii*, *N. plantarum* and *N. pyridinolyticus*, each form distinct phylogenetic lineages. However, in a phylogenetic analysis including other taxa, *Nocardioide*s species did not form a monophyletic cluster. In particular, *N. pyridinolyticus* and *N. jensenii* formed lineages that were separate from the cluster that contained the type species of the genus *Nocardioide*s, *N. albus*, and most other *Nocardioide*s species.

By aligning 16S rDNA sequences of *Nocardioide*s species, species-specific sequences were identified (Park et al., 1998) and were used for design of species-specific primers. These primers are: 5'-ACCGGATACGACAACCGATT-3' (*Escherichia coli*, positions 174-193) for *N. albus* plus *N. luteus*; 5'-TGTAACCTCTTTCAGC GGG-3' (*E. coli*, positions 427-446) for *N. jensenii*; 5'-AGGCGGTCTCTGGAATGTT-3' (*E. coli*, positions 729-749) for *N. plantarum*; and 5'-ATAGGGGTCTCTTTGATACT-3' (*E. coli*, positions 1016-1038) for *N. simplex*. These form the basis of a rapid multiplex polymerase chain reaction (PCR) test to identify *Nocardioide*s species. In this test, all the species-specific primers and one universal reverse primer are mixed in a single reaction tube, and the species is identified by the size of PCR product. When representative strains of *Nocardioide*s species are studied, the PCR products are clearly distinguished by their sizes in agarose gel electrophoresis (Fig. 4). In the multiplex PCR analysis, products of the type strains of *N. albus* and *N. luteus* appear at the same positions. The type strains of *N. jensenii*, *N. plantarum*, and *N. simplex* give PCR products of 1099, 827 and 529 bp, respectively. Products from additional strains previously identified as *N.*

Fig. 4. Agarose gel electrophoresis of amplification products obtained by multiplex PCR from representative strains of the genus *Nocardioide*s. Lanes: M, 100 bp DNA ladder (Gibco BRL, Gaithersburg, MD, USA); 1, *N. albus* KCTC 9186^T; 2, *N. luteus* KCTC 9575^T; 3, *N. jensenii* KCTC 9134^T; 4, *N. plantarum* NCIMB 12834^T; 5, *N. simplex* KCTC 9106^T; N, species-specific PCR products obtained from four primer sets electrophoresed together.

albus and *N. simplex* appear at the same positions as those of the type strains of corresponding species. Thus the multiplex PCR assay rapidly identifies some *Nocardioide*s species and could probably be applied to other recently added *Nocardioide*s species, by design of species-specific primers.

Applications

Only a few *Nocardioide*s strains produce antibiotics (Ogawara et al., 1985; Dellweg et al., 1988; Sanglier et al., 1993). Strain ATCC 39419, which produces a novel anti-tumor antibiotic, sandramycin, was originally assigned to *Nocardioide*s (Matson and Bush, 1989), but has recently been classified as a member of a new genus *Kribbella* (Park et al., 1999). *Nocardioide*s strains can perform chemical and enzymatic modifications of complex compounds (Nobile and Belleville, 1958; Behrend and Heesche-Wagner, 1999; Patel et al., 2000) and produce some industrially useful enzymes (Hanson et al., 1994; Jun et al., 1994; Masson et al., 1995; Nishimoto et al., 1996; Siddiqui et al., 2000). Some strains of *N. simplex* oxidize cholesterol (Arima et al., 1969; Nagasawa et al., 1969). Many *Nocardioide*s strains play an important role in bioremediation. They degrade a variety of pollutants, including alkanes (Iizuka and Komagata, 1964; Hamamura and Arp, 2000; Hamamura et al., 2001), pyridine (Lee et al., 1994; Yoon et al., 1997c), phenols (Rajan et al., 1996; Cho et al., 1998b; Cho et al., 2000; Ebert et al., 1999; Männistö et al., 1999; Männistö et al., 2001; Yoon et al., 1999), phenanthrene (Iwabuchi et al.,

1998c), and others (Golovleva et al., 1990). The type strain of *N. jensenii* can degrade dinitro-*o*-cresol herbicides (Gundersen and Jensen, 1956), and other *Nocardioide*s strains can also degrade herbicides (Travkin et al., 1997; Topp et al., 2000). Some enzymes that degrade pollutants have been characterized (Travkin et al., 1997; Travkin et al., 1999; Iwabuchi et al., 1998c; Saito et al., 1999), and those which degrade phenanthrene have been studied in detail (Iwabuchi and Harayama, 1997; Iwabuchi and Harayama, 1998a; Iwabuchi and Harayama, 1998b; Saito et al., 1999). In the phenanthrene degradation pathway, the structure of the ring cleavage product of an intermediate (1-hydroxy-2-naphthoate) has been determined (Adachi et al., 1999). The gene encoding the enzyme phenanthrene dioxygenase has been cloned, sequenced, and expressed in a functional form in *E. coli* (Saito et al., 2000). Consequently, *Nocardioide*s strains may have a role in bioremediation and detoxification of contaminated regions (Männistö et al., 1999; Männistö et al., 2001; Topp et al., 2000).

Acknowledgments. This work was supported by grants HSS0310134 and an NRL research program (grants M10104000294-01J000012800 and NLW0070111) from the Ministry of Science and Technology (MOST) of South Korea. We are grateful to Dr. Hyun Woo Oh for kindly providing electron micrographs.
